

SocketTools11

Library Edition

Developer's Guide and Technical Reference
Version 11.0.2218.1855

Introduction

The SocketTools Library Edition includes standard Windows dynamic link libraries (DLLs) which can be used in a wide variety of programming languages such as Visual C++, Visual C#, Visual Basic and Delphi. The Library Edition is ideal for the developer who requires the high performance, minimum resource utilization and flexibility of a lower level interface, without the inherent overhead of ActiveX components or the .NET Framework. The SocketTools Library Edition API has over 950 functions which can be used to develop applications that meet a wide range of needs. SocketTools covers it all, including uploading and downloading files, sending and retrieving email, remote command execution, terminal emulation, and much more.

The SocketTools Library Edition includes support for the industry standard Transport Security Layer (TLS) and Secure Shell (SSH) protocols which are used to ensure that data exchanged between the local system and a server is secure and encrypted. The Library Edition implements secure versions of standard protocols such as HTTPS, FTPS, SFTP, SMTPS, POP3S, IMAPS and more. Your data is protected with TLS 1.2 or later using 256-bit encryption and full support for client certificates.

SocketTools also includes an FTP and HTTP server API, as well as a general purpose TCP server API which can be used to create secure custom server applications. There's no need for you to understand the details of certificate management, data encryption or how the security protocols work. All it takes is a few lines of code to enable the security features, and SocketTools handles the rest.

The following are just one of the features in the SocketTools 11 Library Edition:

- Support for Windows 11, Windows Server 2025 and Visual Studio 2022
- Standard Windows dynamic link libraries (DLLs) with no external dependencies
- A comprehensive API with more than 20 libraries and over 950 functions
- Support for both synchronous and asynchronous network connections
- Includes libraries that can be used to create custom client and server applications
- Provides cloud-based application storage and geographical IP location services
- Support for the TLS 1.2 and TLS 1.3 protocols with 256-bit AES encryption
- Support for both implicit and explicit TLS connections
- Support for the SSH protocol and integrated support for SFTP as part of the FTP API
- Support for standard and secure proxy servers using FTP and HTTP
- Support for using client and server certificates in PKCS #12 format
- Thread-safe implementation with full support for multithreaded applications
- An extensive Developer's Guide and online Technical Reference
- Easy redistribution for any number of applications and end users

Developer's Guide

To help you get started using SocketTools, the new Developer's Guide covers a variety of programming topics related to SocketTools, as well as an overview of each of the libraries included in the product. Even if you have experience working with previous versions of SocketTools, we recommend you review the Developer's Guide. If you are using a language other than Visual C++, you'll also find some very helpful information about how to make the most of SocketTools in other programming languages such as C#, Visual Basic and Delphi.

Technical Reference

The Technical Reference provides extensive documentation on all of the functions in each of the SocketTools libraries. It's here that you'll find information on how a function should be called, what the arguments are and what options are available. If it is your first time using a particular library, we recommend that you first read the overview of that library in the Developer's Guide.

SocketTools Licensing Information

The SocketTools Library Edition License Agreement provides you with a single developer license and the right to redistribute the dynamic link libraries (DLLs) included with this product without any additional royalties or runtime licensing fees.

Evaluation Licenses

When you install SocketTools, you are given the option of entering a serial number or proceeding with the installation without a serial number. If you install SocketTools without a serial number, an evaluation development license will be created which is valid for a period of thirty (30) days from the date of installation. The product is fully functional during this evaluation period; however the SocketTools libraries may not be redistributed to third-parties. After the evaluation period has ended, you must either purchase a development license or remove SocketTools from your computer system.

Runtime Licensing

When you install SocketTools with a serial number, a runtime license key will be automatically generated for you and stored in a file named `csrtkey11.h` in the Include folder where you've installed the product. There are similarly named files for other languages, such as `csrtkey11.bas` for Visual Basic and `csrtkey11.pas` for Delphi. These files define the SocketTools runtime licensing key which must be passed to the Initialize function in the library that you are using. If you are using a language that does not have a license key already defined for it, you can create a text file that contains the license key using the License Manager utility. More information about that utility is provided below.

The runtime license key is a null terminated string that is unique to your licensed copy of SocketTools. The runtime license key is not the same as your serial number and should only be embedded in your compiled application. If you provide source code for your product, you cannot include the runtime key with the source code. The same runtime license key should be used for all of the libraries.

If you install SocketTools with an evaluation license, then the runtime license key will be defined as a null pointer or empty string. This will allow the libraries to function on a system with a valid evaluation license, but they will not function on any other system. You must purchase a license and generate a runtime license key before redistributing an application which uses one or more of the SocketTools libraries.

License Manager

Included with your copy of SocketTools is a License Manager utility. This program enables you to see what components have been installed and registered on your system, as well as display information about your SocketTools license. If you need to create a new runtime license key, you can use this utility to do so. Select **License | Header File** from the menu and choose the type of file that you wish to create. For more information about how the License Manager can be used, please refer to the online help file that is included with the utility.

SocketTools 11 Upgrade Information

This section will help you upgrade an application written using a previous version of the SocketTools Library Edition. In most cases, the modifications required will be minimal and may only require a few edits and recompiling the program. However, it is recommended that you review this entire document so that you understand what changes were made and how those changes can be implemented in your software.

Supported Platforms

SocketTools 11 is supported on Windows 7, Windows Server 2008 R2 and later versions. Earlier versions of the operating system, including Windows XP and Windows Vista are no longer supported by Microsoft and cannot be used with SocketTools. We recommend using the latest release of either Windows 10 or Windows 11.

Developers who are redistributing applications which target Windows 11 or Windows Server 2025 should upgrade to ensure compatibility with the platform and current development tools. Secure connections require TLS 1.2 or later and most services will no longer accept connections from a client using SSL 3.0 or TLS 1.0.

Development Tools

As standard Windows dynamic link libraries, SocketTools 11 may be used with virtually any programming language which can call exported functions in a DLL, either by name or by ordinal. Import libraries are provided for Visual C++ in both x86 and x64 COFF format, and for Borland's C++ compilers in OMF32 and ELF64 format. Other languages should use the conventions appropriate for calling an exported function, such as the Declare statement in Visual Basic. Although the libraries may be used with .NET languages, it is recommended you use the SocketTools .NET Edition if you are creating applications for the .NET Framework.

SocketTools Header Files

In SocketTools 11 all of the library constants, functions and C++ classes are in a single header file named **cstools11.h**. This header file also includes the error codes that are defined in a separate header file named **cserror11.h**. There are three special macros that can be defined to control how applications are built using the SocketTools libraries:

CSTOOLS_NO_LIBRARIES

Visual C++ and Borland C++ supports a pragma which can be used to automatically specify the names of libraries that the compiler should attempt to link with in order to resolve function calls. By default, it is not necessary to explicitly specify the names of the SocketTools import libraries to link to. However, if you wish to explicitly link to specific import libraries, then define this macro prior to including the cstools11.h header files.

CSTOOLS_NO_NAMESPACE

When compiling a C++ application, the SocketTools functions are defined in a namespace called SocketTools. This prevents the possibility of conflicts with functions of the same name that may be used in other libraries. If you prefer the functions to be defined in the global namespace instead, then define this macro prior to including the cstools11.h header file.

CSTOOLS_NO_CLASSES

When compiling a C++ application, class wrappers for the SocketTools API are automatically included by default. Defining this macro prevents this, and only the API function prototypes will be declared. It is important to note that this only affects programs written using C++. The class wrappers will not be included for standard C programs, regardless if this macro is defined or not.

SocketTools C++ Class Wrappers

The C++ class wrappers for the SocketTools libraries have been moved from a separate file into the cstools11.h header file, and are now automatically included whenever a C++ program is compiled. The classes have been designed for compatibility with a variety of C++ compilers; however, there are certain features

which are only available if the application is compiled using the Microsoft Foundation Classes (MFC) or Active Template Library (ATL). For example, if an application is built using MFC, each class is derived from CObject and there are additional overloaded methods implemented which support the use of objects like CString. If the application is built without using MFC, or a different C++ compiler is used, those methods will not be available.

Upgrading Projects

If you are upgrading from earlier versions, most applications will be source code compatible with the SocketTools 11 API. In most cases, all you will need to do is install the current version, update the header file and import library references, and then recompile your application. Note that the library file names have changed, as have the export function ordinals. If your build projects use the **SocketTools10** environment variable to specify the location of the header files and import libraries, you need to change it to use **SocketTools11**. This environment variable is automatically defined during the installation process.

The SocketTools 11 libraries are not binary compatible with the earlier versions of the SocketTools libraries and cannot be used as drop-in replacements. If you have declared functions by ordinal in your application (something not typically done), those values have changed and must be updated. If you have declared the exported functions by name, you will be able to reference the new libraries using the same names.

Your runtime license key has changed for SocketTools 11, which will require you to define the new key in your application when calling the initialization functions for each API. As with previous versions of SocketTools, you can use the License Manager utility to generate a file which contains the runtime key you should use. The SocketTools 10 and earlier runtime license keys are not valid for the version 11 libraries and an error will be returned if an invalid runtime key is specified.

With SocketTools 11, secure connections will use TLS 1.2 or later. By default, the libraries will not support connections to servers which use older, less secure versions of TLS or any version of SSL. They will also no longer use weaker cipher suites that incorporate insecure algorithms, such as RC4 or MD5. For applications that require secure connections, it is recommended you use the current build of Windows 10 or Windows 11 with all security updates applied.

It is possible to force the APIs to use earlier versions of TLS for backwards compatibility with older servers. This is done by explicitly setting the *dwProtocol* member of the SECURITYCREDENTIALS structure to specify the protocol version required. However, this is not generally recommended because using SSL 3.0 or TLS 1.0 may cause servers to immediately reject the connection attempt.

The following lists the changes that developers should be aware of when migrating from earlier versions:

- The name of the primary header file is **cstools11.h** and the **cserror11.h** header file defines the error code values. The **csrtkey11.h** header file defines the runtime license key for this version of SocketTools. The runtime license key is normally generated automatically when SocketTools is installed with a valid serial number. It can also be generated using the License Manager utility installed with SocketTools.
- When using C or C++, the **cstools11.h** header file should be included before **Windows.h** to ensure that the compiler does not try to include the deprecated Windows Sockets 1.1 header file. Failure to do so can result in compiler warnings about duplicated macros and function prototypes.
- If you are using the Embarcadero C++ compiler, additional checks are imposed to ensure the SocketTools header files are included before **WinInet.h** and **Vcl.h** files. This prevents conflicts between our APIs and function prototypes defined in those header files.
- The name for each of the DLLs and import libraries has been changed with the new version. Applications written using previous versions of SocketTools must be updated to use the new file names.
- Some constant values have changed and added. This will not impact applications that used the defined macros, but may impact any application which uses hard-coded numeric values, rather than constants or

macros.

Functions in earlier versions of SocketTools that accepted an IPv4 address as a 32-bit integer value have changed to use the new `INTERNET_ADDRESS` structure. If your application stores an IP address in a binary format, you will need to update that code. It is generally recommended that you store IP addresses in their string format, and you should allocate at least 40 characters for the string. That will be large enough to handle both IPv4 and IPv6 addresses.

Most of the networking APIs have an option to force the library to establish an IPv6 network connection. By default, the libraries will still give preference to using IPv4 for backwards compatibility. Note that using options which only establish connections using IPv6 may prevent applications from working correctly on older versions of Windows.

Applications which continue to use SocketTools 10 and earlier libraries can be installed side-by-side with the version 10 libraries. It is recommended that you redistribute the libraries in the same folder as your application executable, rather than a shared system folder such as `C:\Windows\SysWOW64` or `C:\Windows\System32`. It is not recommended that you attempt to use different versions of the libraries within the same application.

Library File Names

The file names of the dynamic link libraries and import libraries have changed with the new version. The following table lists the new names. For more information, refer to the [Redistribution](#) section.

File Name	Import Library	Description
csdnsv11.dll	csdnsv11.lib	Domain Name Service Library
csftpv11.dll	csftpv11.lib	File Transfer Protocol Library
csftsv11.dll	csftsv11.lib	File Transfer Server Library
cshtpv11.dll	cshtpv11.lib	Hypertext Transfer Protocol Library
cshtsv11.dll	cshtsv11.lib	Hypertext Transfer Server Library
csicmv11.dll	csicmv11.lib	Internet Control Message Protocol Library
csmapv11.dll	csmapv11.lib	Internet Message Access Protocol Library
csmsgv11.dll	csmsgv11.lib	Mail Message Library
csmtpv11.dll	csmtpv11.lib	Simple Mail Transfer Protocol Library
csncdv11.dll	csncdv11.lib	File Encoding Library
csnvtv11.dll	csnvtv11.lib	Terminal Emulation Library
csnwsv11.dll	csnwsv11.lib	Network News Transfer Protocol Library
cspopv11.dll	cspopv11.lib	Post Office Protocol Library
csrshv11.dll	csrshv11.lib	Remote Command Protocol Library
csrssv11.dll	csrssv11.lib	Syndicated News Feed Library
cstimv11.dll	cstimv11.lib	Time Protocol Library
cstntv11.dll	cstntv11.lib	Telnet Protocol Library
cstshv11.dll	cstshv11.lib	Secure Shell Protocol Library
cstxtv11.dll	cstxtv11.lib	Text Messaging Library
cswebv11.dll	cswebv11.lib	Web Services Library

cswhov11.dll	cswhov11.lib	Whois Protocol Library
cswskv11.dll	cswskv11.lib	Windows Sockets (SocketWrench) Library

SocketTools Evaluation License

If you install SocketTools without registering a serial number, the product will be installed with an evaluation license that is valid for a period of thirty (30) days. During this trial period, the SocketTools libraries are fully functional and can be used on the development system where the product was installed. If you need to extend the evaluation period, please contact the Catalyst Development sales office by email at sales@sockettools.com or by telephone at +1 760-228-9653, Monday through Friday during normal business hours.

Redistribution Restrictions

When using an evaluation copy of SocketTools, you cannot redistribute the libraries to another system. If you build an application using an evaluation license, it will function correctly on the development system but will fail with an error on any system that does not have a license. Once you have purchased a development license, you should recompile your application before redistributing it to an end-user. If you need to test your application on another system during the evaluation period, you must install an evaluation copy of SocketTools on that system.

Runtime Licensing

When you purchase a development license, a runtime license key will be generated for you which will be included in your applications. This runtime key must be passed to the library's Initialize function in order to use the product. If SocketTools is installed as an evaluation copy, that runtime license key will be defined as a NULL pointer or an empty string and the application cannot be redistributed until a valid key is created. If you have previously installed an evaluation copy of SocketTools and then purchased a license, you can create the runtime license key using the License Manager utility.

For more information, refer to the [Licensing](#) and [Library Initialization](#) sections.

SocketTools Library Redistribution

The SocketTools license permits the use of the libraries to build application software and redistribute that software to end-users. There are no restrictions on the number of products in which the libraries may be used. However, if SocketTools has been installed with an evaluation license, any products built using its libraries cannot be redistributed to another system until a licensed copy of the toolkit has been purchased.

System Requirements

SocketTools is supported on Windows 32-bit and 64-bit desktop and server platforms. The minimum required desktop platform is Windows 7 with Service Pack 1 (SP1) installed. The minimum required server platform is Windows Server 2008 R2 with Service Pack 1 (SP1) installed. It is recommended that the current service pack be installed for the operating system, along with the latest Windows updates available from Microsoft. Some features may require Windows 10 or later versions of the platform. When this is the case, it will be noted in the documentation.

Windows XP and Windows Vista are no longer supported. SocketTools is designed for Windows 7 as the minimum operating system version and will not work correctly on earlier versions of Windows. Although Windows 7 and Windows 8 are no longer supported by Microsoft, SocketTools components will continue to function on those platforms.

Library Redistribution

For applications created using one or more SocketTools libraries, the DLL must be distributed along with the application. The library has no external dependencies, other than standard Windows libraries that are part of the base operating system. In particular, the SocketTools libraries do not use the Microsoft Foundation Classes, nor do they require the Visual C++ Runtime library. The libraries are standard Windows DLLs and do not require COM registration.

If SocketTools is installed on a 64-bit version of Windows, the 32-bit DLLs are installed in the C:\Windows\Syswow64 folder and the 64-bit DLLs are installed in the C:\Windows\System32 folder. When redistributing one or more of the libraries, it is important to make sure that you are selecting the correct version, which is determined by the development tool used and the target platform. For example, if you are using Visual Studio 2019 and target the Win32 platform, then you should only redistribute the 32-bit DLL, regardless if the target system is the 32-bit or 64-bit version of Windows. This is because 32-bit programs can only reference 32-bit libraries. When the application is installed on 64-bit Windows, it will be executed by the WoW64 subsystem which provides a 32-bit environment for the application.

Version Information

The SocketTools libraries have information embedded in them which provides version information to an installation utility. This information called the version resource, specifies the version number as well as other information about the library. If you are using a third-party or in-house installation program, it is extremely important that the program knows how to use this information.

For example, if you are deploying an application which uses the File Transfer Protocol library, the setup program must determine if that library has already been installed on the target system. If it has, it must compare the version resource information in the two libraries. It should only overwrite the library if the version that you have included with your application is later than the one installed on the system. An installation program which overwrites the library without checking the version number may cause the application to fail unexpectedly on the end user's system.

Installation Directory

It is recommended that you install the SocketTools libraries in the same folder with the application that uses them. It is not recommended that you install the libraries under the Windows system folder on an end-user system. If you choose to install the libraries in the Windows system folder, you must ensure that the installer

makes the appropriate registry entries to indicate that they are shared files. Failure to do so can result in the libraries being removed if the user uninstalls your application, which may cause other applications to fail.

If your installer package creates a 32-bit executable and you're deploying a 64-bit application, the installer must be capable of detecting that it is running on a 64-bit system and can disable filesystem redirection to ensure that the 64-bit libraries are installed in the correct location. Consult the documentation for your installer to determine if it is 64-bit compatible.

Windows Install Packages

To help simplify deployment, SocketTools includes MSI (Windows Installer) packages you can use to install the SocketTools libraries on end-user systems. These packages are found in the **Redist** folder where you've installed SocketTools.

Package Name	Description
cstools11_library_x86.msi	SocketTools 11 redistributable libraries for 32-bit applications. This installer is what developers should use if they are targeting the x86 platform and want their software to run on both 32-bit and 64-bit versions of Windows.
cstools11_library_x64.msi	SocketTools 11 redistributable libraries for 64-bit applications. This installer should only be used if 64-bit development tools were used to build the application, and can only be installed on 64-bit versions of Windows.

If you're redistributing a 32-bit application, then all you need is the x86 installer package. If you're redistributing a 64-bit application, then you need the x64 installer package. The installer packages will make sure the libraries are installed in the correct shared Windows folders and will perform the appropriate version checking.

If you have your own installer for your software, then you can redistribute those MSI packages with your installation and use the **msiexec** command to perform the installation. For example, this would install and register the 32-bit libraries with no UI displayed:

```
msiexec /qn /I cstools11_library_x86.msi
```

For the complete list of command line options for **msiexec**, refer to the [Windows App Development](#) documentation.

Technical Support

Catalyst Development is committed to providing quality technical support for our products and we offer several different support options designed to meet the needs of our customers. Technical support by email is available for installation, development and redistribution issues related to the purchased product. There are also paid support options available for customers who require additional assistance.

Standard Support

Registered developers have access to a variety of free technical support resources and we always encourage developers to review our online documentation and knowledge base to determine if the question has already been answered.

[Frequently Asked Questions](#)

A collection of answers to the most frequently asked questions about a product. General questions about features, functionality and platform compatibility are answered here. The product FAQ is also recommended reading for any developer who is evaluating our software.

[Knowledge Base](#)

A searchable online database of solutions to hundreds of common technical questions and problems. The articles provide detailed information, including background information, workarounds and the availability of updates to resolve the problem. This is the first place that most developers should check to determine if the question or problem that they're having has already been addressed.

[Online Documentation](#)

A comprehensive collection of online help for our products. Our online help is useful to evaluators who are interested in learning about how our components work and for developers who would like access to the most current reference material.

[Release Notes](#)

Information about the latest changes, improvements and corrections made to the current version SocketTools. The release notes can reflect changes that affect all SocketTools editions, as well as updates to a component in a specific edition. If you are upgrading from a previous release, it's recommended that you review the release notes.

Priority Support

For developers who require additional support, Priority Support offers a guaranteed, priority response to technical support issues on the same business day. Corrections which require a source code change and/or documentation change to resolve a problem will be made available as a hotfix at no additional charge, and whenever there is a new product update or hotfix, you will be automatically notified by email.

Premium Support

For developers who have critical support needs, an annual Premium Support agreement offers priority email support and a guaranteed four hour response time during business hours. This support option also includes all of the other benefits of priority support, including hotfixes, source code analysis and assistance with example code. In addition, Premium Support also includes free upgrades if a new version of the product is released while your support agreement is active, ensuring that you're always working with the latest version.

License Agreement

This License Agreement is a legal agreement between you, either as an individual or a single entity ("Developer"), and Catalyst Development Corporation ("Catalyst") for the software product identified as "SocketTools Library Edition" ("Software" or "Software Product"). The Software Product includes executable programs, redistributable modules, controls, and dynamic link libraries ("Components" or "Software Components"), electronic documentation, and may include associated media and printed materials.

Installing this Software Product on to a hard disk or any other storage device of a computer, or loading any of the Components into the memory of any computer, constitutes use of the Software and shall acknowledge your acceptance of the terms and conditions of this License Agreement and your agreement to bound thereby.

1. GRANT OF LICENSE

Catalyst Development grants you as an individual, a personal, non-exclusive, non-transferable license to install the Software Product using an authorized serial number. If you are an entity, Catalyst grants you the right to appoint an individual within your organization to use and administer the Software Product subject to the same restrictions enforced on individual users. You may not network the Software or otherwise use it on more than one workstation or computer at the same time. Contact Catalyst for more information regarding multi-developer site licensing.

You may install the Software Product on one or more workstations or computers expressly for the purposes of evaluating the performance of the Software for a period of no more than thirty (30) days. If continued use of the Software is desired after the evaluation period has expired, then the Software Product must be purchased and/or registered with Catalyst Development for each computer or workstation. The Software Product must be removed from all unregistered workstations or computers after the evaluation period has expired.

2. COPYRIGHT

Except for the licenses granted by this agreement, all right, title, and interest in and to the Software Product (including, but not limited to, all copyrights in any executable programs, modules, controls, libraries, electronic documentation, text and example programs), any printed materials and copies of the Software Product are owned by Catalyst Development. The Software Product is protected by copyright laws and international treaty provisions. Therefore you must treat the Software Product like any other copyrighted material except that you may (i) make one copy of the Software solely for backup or archival purposes, or (ii) transfer the Software to a single hard disk, provided you keep the original solely for backup or archival purposes. You may not copy any printed materials that may accompany the Software Product. All rights not specifically granted in this Agreement, including Federal and International Copyrights, are reserved by Catalyst Development.

3. REDISTRIBUTION

(a) In addition to the rights granted in section 1, you are granted the right to use and modify those portions of the Software designated as "example code" for the sole purposes of designing, developing, and testing your software product, and to reproduce and distribute the example code, along with any modifications thereof, only in object code form, provided that you comply with section 3(c).

(b) In addition to the rights granted in section 1, you are granted a non-exclusive, royalty-free right to reproduce and distribute the object code version of any portion of the Software Product, along with any modifications thereof, in accordance with the above stated conditions.

(c) If you redistribute the sample code or redistributable components, you agree to: (i) distribute the redistributables in object code only, in conjunction with and as a part of a software application product developed by you which adds significant and primary functionality to the Software; (ii) not use Catalyst Development's name, logo, or trademarks to market your software application product; (iii) include a valid copyright notice on your software product ; (iv) indemnify, hold harmless, and defend Catalyst Development from and against any claims or lawsuits, including attorney's fees, that arise or result from the use or

distribution of your software application product; (v) not permit further distribution of the redistributables by your end user.

4. UPGRADES

If this copy of the Software is an upgrade from an earlier version of the Software, you must possess a valid full license to a copy of an earlier version of the Software to install and/or use this upgrade copy. You may continue to use each earlier version copy of the Software to which this upgrade copy relates on your computer after you receive this upgrade copy, provided that, (i) the upgrade copy and the earlier version copy are installed and/or used on the same computer only and the earlier version copy is not installed and/or used on any other computer; (ii) you comply with the terms and conditions of the earlier version's end user license agreement with respect to the installation and/or use of such earlier version copy; (iii) the earlier version copy or any copies thereof on any computer are not transferred to another computer unless all copies of this upgrade copy on such computer are also transferred to such other computer; and (iv) you acknowledge and agree that any obligation Catalyst may have to support and/or offer support for the earlier version of the Software may be ended upon availability of the upgrade.

5. LICENSE RESTRICTIONS

You may not rent, lease or transfer the Software. You may not reverse engineer, decompile or disassemble the Software, except to the extent applicable law expressly prohibits the foregoing restriction. You may not alter the contents of a hard drive or computer system to enable the use of the evaluation version of the Software for an aggregate period in excess of the evaluation period for one license. Without prejudice to any other rights, Catalyst Development may terminate this License Agreement if you fail to comply with the terms and conditions of the agreement. In such event, you must destroy all copies of the Software Product.

6. CONFIDENTIALITY

(a) The Software contains information or material which is proprietary to Catalyst Development ("Confidential Information"), which is not generally known other than by Catalyst, and which you may obtain knowledge of through, or as a result of the relationship established hereunder with Catalyst. Without limiting the generality of the foregoing, Confidential Information includes, but is not limited to, the following types of information, and other information of a similar nature (whether or not reduced to writing or still in development): designs, concepts, ideas, inventions, specifications, techniques, discoveries, models, data, object code, documentation, diagrams, flow charts, research, development, methodology, processes, procedures, know-how, new product or new technology information, strategies and development plans (including prospective trade names or trademarks).

(b) Such Confidential Information has been developed and obtained by Catalyst by the investment of significant time, effort and expense, and provides Catalyst with a significant competitive advantage in its business.

(c) You agree that you shall not make use of the Confidential Information for your own benefit or for the benefit of any person or entity other than Catalyst, except for the expressed purposes described in this section, in accordance with the provisions of this Agreement, and not for any other purpose.

(d) You agree to hold in confidence, and not to disclose or reveal to any person or entity, the Software, other related documentation, your product Serial Number or any other Confidential Information concerning the Software other than to such persons as Catalyst shall have specifically agreed in writing to utilize the Software for the furtherance of the expressed purposes described in this section, in accordance with the provisions of this Agreement, and not for any other purpose.

(e) You acknowledge the purpose of this section is to protect Catalyst Development's ability to limit the use of the data and the Software generally to licensees, and to prevent use of Confidential Information concerning the Software by other developers or vendors of software.

7. CONTINUATION OF SERVICE

Some features of the Software may require the use of remote servers under the control of Catalyst

Development to provide specific services. Catalyst makes no warranty as to the availability of these services and reserves the right to discontinue these services at any time and without warning. These services may only be accessed using the Application Programming Interfaces (API) provided by the Software Product and access is limited to licensees and evaluation users of the Software.

We may suspend or terminate your access to these services without liability if (i) we reasonably believe that the services are being used (or have been or will be used) in violation of the Agreement, (ii) we reasonably believe that suspending or terminating your access is necessary to protect our network or our other customers, or (iii) the suspension or termination is required by law. We will give you reasonable advance notice of suspension or termination under this section and a chance to cure the grounds on which the suspension or termination is based, unless we determine, in our reasonable commercial judgment, that an immediate suspension or termination is necessary to protect Catalyst or its other customers from imminent and significant operational or security risk.

8. LIMITED WARRANTY

If within thirty days of your purchase of this software product, you become dissatisfied with the Software for any reason, you may return the software to Catalyst Development (or your dealer, if you did not purchase it directly from Catalyst) for a refund of your purchase price. To return the Software, you must contact Catalyst Development and obtain a Return Material Authorization (RMA) number. Catalyst will not accept returns of opened or installed software without an RMA number. Returns may be subject to the deduction from your purchase price of a restocking fee and all shipping costs.

CATALYST PROVIDES NO REMEDIES OR WARRANTIES, WHETHER EXPRESS OR IMPLIED, FOR ANY SAMPLE APPLICATION CODE, TRIAL VERSION AND THE NOT FOR RESALE VERSION OF THE SOFTWARE. ANY SAMPLE APPLICATION CODE, TRIAL VERSION AND THE NOT FOR RESALE VERSION OF THE SOFTWARE ARE PROVIDED "AS IS".

CATALYST DISCLAIMS ALL OTHER WARRANTIES, EITHER EXPRESS OR IMPLIED, INCLUDING BUT NOT LIMITED TO IMPLIED WARRANTY OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE, WITH RESPECT TO THE SOFTWARE, THE ACCOMPANYING WRITTEN MATERIALS, AND ANY ACCOMPANYING HARDWARE.

9. LIMITATION OF LIABILITY

IN NO EVENT SHALL CATALYST OR ITS SUPPLIERS BE LIABLE FOR ANY DAMAGES WHATSOEVER (INCLUDING, WITH LIMITATION, INCIDENTAL, CONSEQUENTIAL, SPECIAL, OR EXEMPLARY DAMAGES OR LOST PROFITS, BUSINESS INTERRUPTION, OR OTHER PECUNIARY LOSS) ARISING OUT OF THE USE OR INABILITY OF THIS CATALYST PRODUCT, EVEN IF CATALYST HAS BEEN ADVISED OF SUCH DAMAGES.

APART FROM THE FOREGOING LIMITED WARRANTY, THE SOFTWARE PROGRAMS ARE PROVIDED "AS-IS", WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED. THE ENTIRE RISK AS TO THE PERFORMANCE OF THE PROGRAMS IS WITH THE PURCHASER. CATALYST DOES NOT WARRANT THAT THE OPERATION OF THE PROGRAMS WILL BE UNINTERRUPTED OR ERROR-FREE. CATALYST ASSUMES NO RESPONSIBILITY OR LIABILITY OF ANY KIND FOR ERRORS IN THE PROGRAMS OR DOCUMENTATION, OF/FOR THE CONSEQUENCES OF ANY SUCH ERRORS. THE LAWS OF THE STATE OF CALIFORNIA GOVERN THIS AGREEMENT.

10. GOVERNMENT-RESTRICTED RIGHTS

United States Government Restricted Rights. The Software and related documentation are provided with RESTRICTED RIGHTS. Use, duplication, or disclosure by the Government is subject to the restrictions set forth in subparagraph (c)(1)(ii) of the Rights in Technical Data and Computer Software clause at DFARS 252.227-7013 or subparagraphs (c)(1) and (2) of the Commercial Computer Software - Restricted Rights at 48 CFR 52.227-19, as applicable. Manufacturer for such purposes is Catalyst Development Corporation, 56925 Yucca Trail #254, Yucca Valley, CA 92284

11. EXPORT CONTROLS

You agree to comply with all relevant regulations, including but not limited to those, of the United States Department of Commerce and with the United States Export Administration Act to insure that the Software is not exported in violation of United States law. You acknowledge that the Software is subject to export regulations and agree that you will not export, re-export, import or transfer the software in violation of any United States or other applicable laws, whether directly or indirectly, and you will not assist or facilitate others in doing so. You acknowledge that you have the responsibility to obtain any export classifications and licenses as may be required to comply with such laws.

12. PROHIBITED DESTINATIONS

The exportation, re-exportation, sale or supply of Catalyst products, software components or documentation, directly or indirectly, from the United States or by a United States citizen wherever located, to Cuba, Iran, North Korea, Sudan, Syria, or any other country to which the United States has embargoed goods, is strictly prohibited without prior authorization by the United States Government. You represent and warrant that neither the United States Bureau of Export Administration nor any other federal agency has suspended, revoked or denied your export privileges. Catalyst products, software components or documentation may not be exported or re-exported to anyone on the United States Treasury Department's list of Specially Designated Nationals or the United States Department of Commerce Denied Person's List or Entity List.

13. GOVERNING LAW

This License is governed by the laws of the State of California, without reference to conflict of laws principles. Any controversy or claim arising out of or relating to this contract, or the breach thereof, shall be settled by arbitration administered by the American Arbitration Association ("AAA") under its Commercial Arbitration Rules, and judgment on the award rendered by the arbitrator(s) may be entered in any court having jurisdiction thereof. The arbitrator shall be a retired judge or attorney with at least 15 years commercial law experience and shall be selected either by mutual agreement of the parties or by AAA's selection process. The parties shall be entitled to take discovery in accordance with the provisions of the California Code of Civil Procedure, including but not limited to CCP §1283.05. The arbitration shall be held in San Bernardino, California and in rendering the award the arbitrator must apply the substantive law of the State of California.

14. GENERAL PROVISIONS

This License Agreement contains the complete agreement between the parties with respect to the subject matter hereof, and supersedes all prior or contemporaneous agreements or understandings, whether oral or written. You agree that any varying or additional terms contained in any purchase order or other written notification or document issued by you in relation to the Software licensed hereunder shall be of no effect. The failure or delay of Catalyst to exercise any of its rights under this Agreement or upon any breach of this Agreement shall not be deemed a waiver of those rights or of the breach.

If any provision of this agreement shall be held by a court of competent jurisdiction to be contrary to law, that provision will be enforced to the maximum extent permissible, and the remaining provisions of this agreement will remain in full force and effect.

SocketTools and other trademarks contained in the Software are trademarks or registered trademarks of Catalyst Development Corporation in the United States and/or other countries. Third party trademarks, trade names, product names and logos may be the trademarks or registered trademarks of their respective owners. You may not remove or alter any trademark, trade names, product names, logo, copyright or other proprietary notices, legends, symbols or labels in the Software.

SocketTools Features

The SocketTools libraries can be used in a wide variety of programming languages, including Visual C++, Visual C#, Visual Basic.NET and Visual Basic 6.0, as well as C++ Builder, Delphi, Clarion and a variety of other development environments. Any language which is capable of calling functions exported from a Windows dynamic link library can take advantage of the SocketTools Library Edition.

Features of the SocketTools Library Edition include:

- An efficient architecture designed to reduce the overhead of using other types of components such as ActiveX controls. The libraries in the SocketTools Library Edition are not COM libraries, but rather standard Windows dynamic link libraries which have been optimized for high performance and low resource utilization on the Windows platform.
- There are no external dependencies on third party libraries or components, and each DLL is completely self-contained. We do not require that you redistribute large shared libraries like the Microsoft Foundation Classes or Visual C++ runtime libraries. Not only does this make redistribution of your software easier, it can reduce the overall footprint for applications which do not need to use these libraries themselves.
- An interface which is designed for broad-based compatibility with a variety of programming languages, not just for C or C++ programmers. You won't see functions that only provide complex interfaces, using data types or structures which are difficult or impossible to represent in other programming languages. Following the model of the Windows API, the functions use handles (integer values) to reference client sessions and most data types used as function parameters are null-terminated strings, integers or byte arrays. In those cases where structures are used, they are designed to be compatible with most languages. Simply put, if your programming language can call functions in the Windows API, you can use the SocketTools Library Edition.
- A comprehensive design which supports both high-level operations as well as lower-level functions at the protocol level. For example, the File Transfer Protocol library has functions such as **FtpPutFile** and **FtpGetFile** which allow an application to easily upload and download files in a single function call. It also includes lower-level functions like **FtpOpenFile** to open a file on the server and access it in a fashion similar to traditional file I/O operations.
- Support for both synchronous (blocking) and asynchronous (non-blocking) operation depending on the needs of the application. Asynchronous operation is supported by an event-driven model where the application is notified of networking events by user-defined messages posted to the message queue. Event notification can be enabled, disabled, suspended and resumed completely under the control of the application, giving developers complete freedom in controlling their behavior of their software. Synchronous operation is also fully supported, enabling developers to easily write programs in a procedural "top down" programming style without using an event-driven approach.
- Support for function callbacks during high-level synchronous operations, such as downloading a file or sending an email message. This allows an application to make changes to its user interface, such as updating a progress bar. This enables the developer to take advantage of the simplicity of using high-level functions without sacrificing the flexibility or features expected by the user.
- The Library Edition enables applications to take advantage of security features, such as support for the transport Layer Security (TLS) protocol and 256-bit encryption. The libraries use the Windows CryptoAPI to provide security services, which means there are no third-party security libraries that must be installed by your users. Taking advantage of the security features in the SocketTools Library Edition is as simple as setting a few API options before connecting to the server. The protocol negotiation, data encryption and decryption is handled transparently by the library. From the perspective of the application developer, it is just as if it were a standard connection to the server.

- Libraries which are thread-safe and optimized for applications which use multiple threads. The SocketTools libraries fully support multithreaded applications and implement an internal architecture that insures that client sessions can be safely created and used by multiple threads. Applications can create worker threads and pass client handles to those threads to perform some function and then return the handle back to the original owner or simply terminate the connection.

The SocketTools Library Edition includes everything professional software developers need to create complex programs that take advantage of the standard Internet protocols, enabling developers to focus on their core application technology rather than the details of how to upload a file or retrieve an email message from a server.

Getting Started

SocketTools is a large collection of libraries that can be used to create a variety of applications, so deciding what protocols and libraries you'll need to use will be the first step. SocketTools covers several general categories, and there is some cross-over between libraries in terms of functionality. We'll cover the most common programming needs and discuss what protocols should be used. Note that this section doesn't cover all of the libraries in SocketTools, and more specific information for each library is available within the toolkit.

One thing you'll discover as you start to use SocketTools is that the API was intentionally designed to be consistent between many of the libraries. For example, both the File Transfer Protocol and Hypertext Transfer Protocol libraries can be used to upload and download files, and the functions for both of those libraries are very similar. Once you've become comfortable working with one of the libraries, you'll find it very easy to use the other, related libraries.

File Transfers

- [File Transfer Protocol](#)
- [Hypertext Transfer Protocol](#)

One of the most common requirements for an application is the ability to upload and download files, either over the Internet or between systems on a local intranet. There are two core protocols which are used for file transfers, the File Transfer Protocol (FTP) and the Hypertext Transfer Protocol (HTTP). The decision as to which protocol to use largely depends on whether or not the program must also perform any type of file management on the server. Because many of the functions in the FTP and HTTP APIs are similar, you may wish to use both and simply give your users an option as to which protocol they prefer to use.

If your program needs to upload files or manage the files on the server, we recommend that you use FTP. In addition to uploading and downloading files, FTP can be used to rename or delete files, create directories, list the files in a directory and perform a variety of other functions. On the other hand, if you primarily need to just download files, HTTP can be a better choice. The protocol is simpler and you're less likely to encounter some of the issues that can arise when using FTP from behind a firewall.

It is also an option to use FTP to upload and manage files and HTTP to download files within the same program. The important thing to keep in mind is that if you want to use HTTP and need to upload files, you must make sure that the server has been configured for it. Most web servers do not support the ability to upload files by default; it requires the administrator to specifically enable that functionality.

World Wide Web

- [Hypertext Transfer Protocol](#)

If you need to access documents or execute scripts on a web server, you'll want to use the Hypertext Transfer Protocol (HTTP) library. You can use the library to download files and post data to scripts. The library also supports the ability to upload files, either using the PUT command or by using the POST command, which is the same method used when selecting a file to upload using a form. The library can also be used to execute custom commands, allowing your application to take advantage of features like WebDAV, a distributed authoring extension to HTTP.

Web Services

- [Application Storage Service](#)
- [GeoIP Location Service](#)
- [Text Messaging Service](#)

SocketTools provides secure services that you can use to store and manage application data, obtain geographical location information based on an IP address, and send text messages through SMS gateways. These services use secure, encrypted connections to our servers, and our Web Services library provides a high-level interface to the underlying RESTful service APIs which are used.

Electronic Mail

- [Domain Name Services Protocol](#)
- [Internet Message Access Protocol](#)
- [Mail Message Library](#)
- [Post Office Protocol](#)
- [Simple Mail Transfer Protocol](#)

There are a number of SocketTools libraries which can be used by an application that needs to send email messages or retrieve them from a user's mailbox. The email related libraries can be broken into three groups, those that deal primarily with managing and retrieving messages for a user, those which are used to send messages and those which can be used for either purpose.

The two principal protocols used to manage a user's email are the Post Office Protocol (POP3) and the Internet Message Access Protocol (IMAP). POP3 is the protocol that the majority of Internet Service Providers (ISP) use to give their customers access to their messages. It is primarily designed to enable an application to download the messages from the mail server and store them on the local system. Once all of the messages have been downloaded, they are deleted from the server. The user's mailbox is essentially treated as a temporary storage area.

On the other hand, IMAP is designed to allow the application to manage the messages on the server. You can create new mailboxes, move messages between mailboxes and search for messages. Because IMAP can be used to access specific parts of a message, it's not necessary to download the entire message if you just want to read a specific part of it. In terms of the SocketTools APIs, it's useful to think of the functions in the IMAP library as a superset of those in the POP3 library. You'll find that functions used for accessing messages are very similar, but the IMAP library contains additional functions for managing mailboxes and performing operations that are specific to that protocol, such as the ability to search for messages.

To send an email message to someone, the protocol that you'll use is the Simple Mail Transfer Protocol (SMTP). The SocketTools library supports the standard implementation of this protocol, along with many of the extensions that have been added since its original design. Extended SMTP (ESMTP) provides features such as authentication, delivery status notification, secure connections using TLS and so on. Another library that you may use is the Domain Name Services (DNS) library, which your application can use to determine what servers are responsible for accepting mail for a particular user.

Common to both sending and receiving email messages is the need to be able to create and process those messages. An email message has a specific structure which is defined by a number of standards, collectively called the Multipurpose Internet Mail Extensions (MIME). The SocketTools Mail Message library can be used to create messages in the format, as well as parse existing messages so that your application can access the specific information that it needs. For example, you can use this library to attach files to a message as well as extract a specific file attachment from a message and store it on the local system.

Terminal Sessions

- [Rlogin Protocol](#)
- [Secure Shell Protocol](#)
- [Telnet Protocol](#)
- [Terminal Emulation](#)

If you need to establish an interactive terminal session with a server, there are two protocols that you can use. The most common is the Telnet Protocol; however, there is also the Rlogin protocol which is part of the Remote Command library. Either of these protocols are typically used in conjunction with the Terminal Emulation library, which provides ANSI and DEC VT-220 terminal emulation functions. Used together, the user can login and interact with the server in the same way that they would use a console or character based terminal.

Newsgroups

- [File Encoding Library](#)
- [Mail Message Library](#)
- [Network News Transfer Protocol](#)

If you need to access newsgroups, the Network News Transfer Protocol will enable you to connect, list, retrieve and post articles. Because news articles have a format that is very similar to email messages, the Mail Message library can be used to parse articles that you've downloaded or create new articles to be posted. If you need to attach a file to the article that you're posting, the File Encoding library can be used to encode the file using the yEnc encoding algorithm, which has become the de facto standard on USENET.

General Concepts

This section of the developer's guide will cover the core networking protocols along with the general concepts related to Internet programming. Although it is not necessary to understand the lower level details of network programming in order to use SocketTools, it is useful to be familiar with the basic concepts and terminology.

Application Protocols

Throughout the documentation, you will see the word "protocols" mentioned. There are two general types of protocols that will be discussed in this developer's guide. The first type of protocol will be referred to as networking protocols. They are lower level protocols which define how data is exchanged between two systems. The two networking protocols that will be discussed are the User Datagram Protocol (UDP) and the Transmission Control Protocol (TCP).

Then there are what we will call the application protocols, which use the networking protocols to communicate. Application protocols deal with a specific type of functionality. For example, the File Transfer Protocol (FTP) is used to upload and download files, while the Simple Mail Transfer Protocol (SMTP) is used to send email messages. Conceptually, you can think of the networking protocols as defining the rules for how programs can communicate with one another over the Internet. The application protocols operate at a higher level, defining the rules for how a specific kind of task can be carried out, such as transferring a file from one computer to another.

The application protocols are defined in standards documents called RFCs (Request For Comments) which are maintained by the Internet Engineering Task Force. The following protocols standards are implemented by the SocketTools components:

RFC	Description
792	Internet Control Message Protocol
822	Standard for the Format of ARPA Internet Text Messages
854	Telnet Protocol Specification
868	Time Protocol
954	Nickname/Whois Protocol
959	File Transfer Protocol (FTP)
977	Network News Transfer Protocol
1034	Domain Name Services
1055	Serial Line IP (SLIP)
1282	Rlogin
1288	Finger User Information Protocol
1579	Firewall-Friendly FTP
1661	The Point-to-Point Protocol (PPP)
1738	Uniform Resource Locators
1869	SMTP Service Extensions
1939	Post Office Protocol Version 3
1945	Hypertext Transfer Protocol 1.0
1951	Deflate Compressed Data Format Specification
2045	Multipurpose Internet Mail Extensions (Part One)
2046	Multipurpose Internet Mail Extensions (Part Two)

2047	Multipurpose Internet Mail Extensions (Part Three)
2048	Multipurpose Internet Mail Extensions (Part Three)
2228	FTP Security Extensions
2616	Hypertext Transfer Protocol 1.1
2821	Simple Mail Transfer Protocol (SMTP)
2980	Common NNTP Extensions
3501	Internet Message Access Protocol Version 4

Transmission Control Protocol

When two computers wish to exchange information over a network, there are several components that must be in place before the data can actually be sent and received. Of course, the physical hardware must exist, which is typically either a network interface card (NIC) or a serial communications port for dial-up networking connections. Beyond this physical connection, however, computers also need to use a protocol which defines the parameters of the communication between them. In short, a protocol defines the "rules of the road" that each computer must follow so that all of the systems in the network can exchange data. One of the most popular protocols in use today is TCP/IP, which stands for Transmission Control Protocol/Internet Protocol.

By convention, TCP/IP is used to refer to a suite of protocols, all based on the Internet Protocol (IP). Unlike a single local network, where every system is directly connected to each other, an internet is a collection of networks, combined into a single, virtual network. The Internet Protocol provides the means by which any system on any network can communicate with another as easily as if they were on the same physical network. Each system, commonly referred to as a host, is assigned a numeric value which can be used to identify it over the network. These numeric values are known as IP addresses, and are usually represented as a string value that contains a series of numbers.

There are two versions of TCP/IP and two different IP address formats based on which version of the protocol is being used. For Internet Protocol v4 (IPv4), addresses are 32 bits wide and are represented by a sequence of four 8-bit numbers separated by periods. This is called dot-notation and looks something like **192.168.19.64**. This is the address format that many developers are familiar with because IPv4 continues to be the most commonly used version of the protocol. Internet Protocol v6 (IPv6) is the next generation of IP and it supports a much larger address space as well as a number of other features. IPv6 addresses are 128 bits wide and represented by a sequence of hexadecimal values separated by colons. As expected, this format is much longer than the simple dot-notation used by IPv4 address. A typical IPv6 address will look something like **fd7c:2f6a:4f4f:ba34::a32**, although there are certain shorthand notations that can be used. SocketTools supports both IPv4 and IPv6, and can automatically determine which version of the protocol should be used based on the address. Because IPv4 is still widely used, if given a choice between using IPv4 or IPv6, the SocketTools components will choose IPv4 for backwards compatibility whenever possible. However, an application can choose to exclusively use IPv6 if required.

When a system sends data over the network using the Internet Protocol, it is sent in discrete units called datagrams, also commonly referred to as packets. A datagram consists of a header followed by application-defined data. The header contains the addressing information which is used to deliver the datagram to its destination, much like an envelope is used to address and contain postal mail. And like postal mail, there is no guarantee that a datagram will actually arrive at its destination. In fact, datagrams may be lost, duplicated or delivered out of order during their travels over the network. Needless to say, this kind of unreliability can cause a lot of problems for software developers. What's really needed is a reliable, straightforward way to exchange data without having to worry about lost packets or mixed data.

To fill this need, the Transmission Control Protocol (TCP) was developed. Built on top of IP, TCP offers a reliable, full-duplex byte stream which may be read and written to in a fashion similar to reading and writing a file. The advantages to this are obvious: the application programmer doesn't need to write code to handle dropped or out-of-order datagrams, and instead can focus on the application itself. And because the data is presented as a stream of bytes, existing code can be easily adopted and modified to use TCP.

TCP is known as a connection-oriented protocol. In other words, before two programs can begin to exchange data they must establish a connection with each other. This is done with a three-way handshake in which both sides exchange packets and establishes the initial packet sequence numbers. The sequence number is important because, as mentioned above, datagrams can arrive out of order; this number is used to ensure that data is received in the order that it was sent. When establishing a connection, one program must assume the role of the client, and the other the server. The client is responsible for initiating the connection, while the

server's responsibility is to wait, listen and respond to incoming connections. Once the connection has been established, both sides may send and receive data until the connection is terminated.

Most of the application protocols which are supported by SocketTools use TCP to communicate over the Internet or local intranet. However, it is important to remember that it is not necessary for you to understand how TCP/IP works at the lowest levels in order to use SocketTools. Complex operations such as performing checksums on packets of data to ensure they arrive intact are handled for you automatically. In most cases, the SocketTools API provides functions which are similar to what you would use when reading or writing to a file.

User Datagram Protocol

Unlike TCP, the User Datagram Protocol (UDP) does not present data as a stream of bytes, nor does it require that you establish a connection with another program in order to exchange information. Data is exchanged in discrete units called datagrams, which are similar to IP datagrams. In fact, the only features that UDP offers over raw IP datagrams are port numbers and an optional checksum.

UDP is sometimes referred to as an unreliable protocol because when a program sends a UDP datagram over the network, there is no way for it to know that it actually arrived at its destination. This means that the sender and receiver must typically implement their own application protocol on top of UDP. Much of the work that TCP does transparently (such as generating checksums, acknowledging the receipt of packets, retransmitting lost packets and so on) must be performed by the application itself.

With the limitations of UDP, you might wonder why it's used at all. UDP has the advantage over TCP in two critical areas: speed and packet overhead. Because TCP is a reliable protocol, it goes through great lengths to insure that data arrives at its destination intact, and as a result it exchanges a fairly high number of packets over the network. UDP doesn't have this overhead, and is considerably faster than TCP. In those situations where speed is paramount, or the number of packets sent over the network must be kept to a minimum, UDP is the solution.

A few of the SocketTools libraries use UDP as the method of communicating with a server. The Domain Name Services library and the Time Protocol library both use UDP to request information from a server. The amount of data exchanged is typically very small, and UDP is well suited for those protocols. In addition, the Internet Control Message Protocol uses a special type of IP datagram in order to determine information about a server, such as whether it is reachable and the amount of time that it takes to exchange data with the local system. More information about these protocols will be presented later in the Developer's Guide.

Domain Names

An application must have several pieces of information to exchange data with a program running on another system. The first is the Internet Protocol (IP) address of the computer system on which the other program is running. Although this address is internally represented by a numeric value (either 32 or 127 bits wide), it is typically identified by a logical name called a host name or fully qualified domain name. Host names are divided into several parts separated by periods, called domains. The structure is hierarchical, with the top-level domains defining the type of organization that network belongs to, and sub-domains further identifying the specific network. Everyone who has used a web browser is familiar with host names such as **www.microsoft.com**.

In this figure, the top-level domains are "gov" (government agencies), "com" (commercial organizations), "edu" (educational institutions) and "net" (Internet service providers). The fully qualified domain name is specified by naming the host and each parent sub-domain above it, separating them with periods. For example, the fully qualified domain name for the "jupiter" host would be "jupiter.sockettools.com". In other words, the system "jupiter" is part of the "sockettools" domain (a company's local network) which in turn is part of the "com" domain (a domain used by all commercial enterprises).

To use a host name instead of an IP address to identify a specific system or network, there must be some correlation between the two. This is accomplished by one of two means: a local host table or a name server. A host table is a text file that lists the IP address of a host, followed by the names by which it is known. A name server is a system which can be presented with a host name and will return that host's IP address. This approach is advantageous because the host information for the entire network is maintained in one centralized location, rather than being scattered over every system on the network.

The standard protocol used to convert a host name into an IP address is called the Domain Name Service (DNS) protocol. All of the SocketTools networking libraries have the ability to automatically convert between host names and IP addresses, and in most cases they can be used interchangeably. For example, those functions which require that you specify the name of a server to connect to, you can use either its host name or its IP address. In addition, SocketTools has a library that specifically supports the Domain Name Service protocol, enabling your application to send specialized queries to the name server. Later in the Developer's Guide there will be information about how DNS can be used in a number of different types of applications.

Service Ports

In addition to the IP address of the server, an application also needs to know how to address the specific program that it wishes to communicate with. This is accomplished by specifying a service port, a number between 1 and 65535 that uniquely identifies an application running on the system. A port can be referred to by its number, or by a name that is associated with that number. Like hostnames, service names are usually matched to port numbers through a local file, commonly called services. This file lists the logical service name, followed by the port number and protocol used by the server.

A number of standard service names are used by Internet-based applications and these are referred to as Well Known Services. These services are defined by a standards document and include common application protocols used for transferring files, accessing documents on a webserver or sending and receiving email messages. In most cases, when connecting to a service using the SocketTools libraries, they will default to the appropriate port number for that server. For example, the File Transfer Protocol library has default port values for standard and secure connections. Specifying a different port number is only necessary if you know that the server has been configured to use a non-standard port number.

It is important to remember that a service name or port number is a way to address an application running on a server. Because a particular service name is used, it doesn't guarantee that the service is available, just as dialing a telephone number doesn't guarantee that there is someone at home to answer the call.

Sockets

The previous sections described what information a program needs to communicate over a TCP/IP network. The next step is for the program to create what is called a socket, a communications end-point that can be likened to a telephone. However, creating a socket by itself doesn't let you exchange information, just like having a telephone in your house doesn't mean that you can talk to someone by simply taking it off the hook. You need to establish a connection with the other program, just as you need to dial a telephone number, and to do this you need the address of the application that you want to connect to. This address consists of three key parts: the protocol family, Internet Protocol (IP) address and the service port number.

We've already talked about the IP address and service port, but what's the protocol family? It's a number which is used to logically designate a group of related protocols. Since the socket interface is general enough to be used with several different protocols, the protocol family tells the underlying network software which protocol is being used by the socket. In our case, the Internet Protocol family will always be used when creating sockets. With the protocol family, IP address of the system and the service port number for the program that you want to exchange data with, you're ready to establish a connection.

For the most part, it is not necessary for applications which use the SocketTools libraries to directly make use of the low-level socket interface in order to communicate over the Internet. Instead, SocketTools provides a higher level of abstraction where a connection is identified using a handle to a client session.

SocketTools Handles

Throughout the documentation for the SocketTools functions, you will see references to handles. Windows developers are generally familiar with the concept of handles since they are used throughout the Windows API. In simplest terms, a handle is an unsigned integer value that is used to represent some object in memory. The actual value of the handle is not important and may refer to the memory address of a specific object, or it may be an index into a table of objects. When a handle is created, its value is unique for the life of each object created by the process. It is important that an application never make assumptions about the specific value of a handle. Handle values may be reused for objects that have been destroyed, and there is no guarantee that handle values are assigned in any particular order.

In SocketTools, handles are commonly used to refer to client sessions. A session begins when the library is used to establish a connection with the server and ends when that connection is terminated. The client handle is defined as an unsigned integer type called `HCLIENT` and is returned by those functions which create a new connection. When the connection is terminated, the handle is released, along with any system resources that were allocated for it. An unused handle is identified by the constant `INVALID_CLIENT`. If a function returns this value instead of a valid handle, it indicates that the function has failed. It is important to note that the handles returned by the SocketTools functions are not necessarily socket handles and cannot be used interchangeably with the Windows Sockets API or other Windows kernel functions.

When your application targets the x86 platform, SocketTools handles are 32 bits wide. When you target the x64 platform, the handles are 64 bits wide, however only the lower 32 bits are significant. This means that it is safe to cast a 64-bit SocketTools handle to a 32-bit integer value and then back to a handle if necessary. It is recommended that you always use the appropriate handle type in your code, such as `HCLIENT`. Assumptions about the width of a handle in your program can lead to portability problems if you ever decide to create a 64-bit version of your application.

Security Protocols

Security and privacy is a concern for everyone who uses the Internet, and the ability to provide secure transactions over the Internet has become one of the key requirements for many business applications. The SocketTools Library Edition has the ability to establish secure connections with servers. Although most of the technical issues such as data encryption are handled internally by the library, a general understanding of the standard security protocols is useful when designing your own applications.

When you establish a connection to a server over the Internet (for example, a web server), the data that you exchange is typically routed over dozens of computer systems until it reaches its destination. Any one of these systems may monitor and log the data that it forwards, and there is no way for either the sender or receiver of that data to know if this has been done. Exchanging information over the Internet could be likened to talking with someone in a public restaurant. Anyone can choose to listen to what you're saying, and unless they introduce themselves, you have no idea who they are or if they've even heard what you said.

To ensure that private information can be securely exchanged over the Internet, two basic requirements must be met: there must be a way to send that information so that only the sender and the receiver can understand what is being exchanged, and there must be a way for them to determine that they each are in fact who they claim to be. The solution to the first problem is to use encryption, where a key is used to encrypt and decrypt the data using a mathematical formula. The second problem is addressed by using digital certificates. These certificates are issued by a certificate authority (CA), which is a trusted third-party organization who verifies the individual or company which is issued a certificate are who they claim to be. These two concepts, encryption and digital certificates, are combined to provide the means to send and receive secure information over the Internet.

The Secure Sockets Layer (SSL) protocol was originally developed by Netscape as a way to exchange information securely over the Internet, and is no longer widely used. Improvements to SSL have resulted in the Transport Layer Security (TLS) protocol, and it has become the standard for secure communications over the Internet. Both of these protocols are designed to allow a private exchange of encrypted data between the sender and receiver, making it unreadable by an intermediate system. Using the restaurant analogy, it would be as if two people were speaking in a language that only they could understand. Although someone sitting at the next table could listen in on the conversation, they wouldn't have any idea what was actually being said.

A secure connection, for example between a web browser and a server, begins with what is called the handshake phase where the client and server identify themselves. When the client first connects with the server it sends a block of data to the server and the server responds with its digital certificate, along with its public key and information about what type of encryption it would like to use. Next, the client generates a master key and sends this key to the server, which authenticates it. Once the client and server have completed this exchange, keys are generated which are used to encrypt and decrypt the data that is exchanged. With the handshake completed, a secure connection between the client and server is established. SocketTools handles the handshake phase of the secure connection automatically and does not require any additional programming. If a secure connection cannot be established, an error is returned and the network connection is closed.

After the handshake phase has completed, the client may choose to examine the digital certificate that has been returned by the server. The information contained in the certificate includes the date that it was issued, the date that it expires, information about the organization who issued the certificate (called the issuer) and to whom the certificate was issued (called the subject of the certificate). The client may also validate the status of the certificate, determining if it was issued by a trusted certificate authority and was returned by the same company or individual it was issued to. There may be certain cases where the client determines that there's a problem with the certificate (for example, if the certificate's common name does not match the domain name of the server), but chooses to continue communicating with the server. Note that the connection with the server will still be secure in this case. In other cases, for example if the certificate has expired, the client may choose to terminate the connection and warn the user.

Digital Certificates

With secure connections, digital certificates are used to exchange public keys for data encryption and to provide identification information. This information typically includes the organization that was issued the certificate, its physical location and so on. The certificate itself is used to validate that the public key actually belongs to the entity it was issued to. The certificate also includes information about the Certification Authority (CA) who issued the certificate. The CA is responsible for validating the information provided by that organization, and then digitally signing the certificate. This establishes a relationship between the two so that when others validate the certificate, they know that it has been issued by a trusted third-party. For example, let's say that a company wants to implement a secure site so people can order products online. They would provide information about their company (organizational contacts, financial information and so on) to a trusted third party organization such as Verisign or DigiCert. That organization would then verify that the information they provided was complete and correct, and then would issue a signed certificate to them, which they install on their server. When a user connects to their server and checks the certificate, they see that it was issued by a trusted Certification Authority. In essence, the user is saying that because they trust the Certificate Authority, and the Certificate Authority trusts the company to whom the certificate was issued, they will trust the company as well.

To establish this relationship between the Certification Authority and the organization a certificate is issued to, there needs to be a root certificate which has been signed by the same trusted organization. This serves as the beginning of the certification path that is used to validate signed certificates. Using the above example, on the user's system there is a root certificate for Verisign, signed by Verisign. Root certificates are maintained in the local system's certificate store which is essentially a database of digital certificates. This database is structured so that different types of certificates can be organized in one central location on the system, and a standard interface is provided to enumerate and validate these certificates. Certificates are associated with a store name, allowing them to be easily categorized. For example, root certificates are stored under the name "Root", while a user's personal certificates (along with their private keys) are stored under the name "My".

When the Windows operating system is installed, there is a certificate store that contains the root certificates for the major Certification Authorities. However, there are situations where additional certificates may need to be added to the system. To facilitate this, there is a tool called CertMgr.exe which allows a user to install certificates, as well as export or remove certificates from the certificate store. When managing your system's certificate store, you should take the same care that you do when making changes to the system registry. Inadvertently removing a certificate could result in errors when attempting to access secure systems.

In general, the one situation where certificate management becomes important is when you want to develop your own secure server. This is because your server needs to have a signed certificate to send to the client in order to establish the secure connection. For general-purpose commercial applications, this generally means you would need to obtain a certificate that has been signed by a Certification Authority such as Verisign or DigiCert. This certificate would then be installed in the certificate store on the server. However, for development purposes it may be inconvenient to purchase a certificate. There also may be situations in which an organization wishes to function as its own Certification Authority and issue certificates themselves. This allows the organization to control how certificates are managed and can be ideal for secure applications that are designed for the corporate intranet. A utility for creating self-signed root certificates and server certificates is included with SocketTools.

SocketTools Development

The SocketTools Library Edition provides a comprehensive collection of over eight hundred functions for performing a variety of Internet related programming tasks. Although the size of the SocketTools API may appear daunting, once you begin using the libraries in your own applications you'll find that the various libraries are designed to work together in a cohesive fashion. After you've familiarized yourself with one library, the others will become much simpler to use.

Throughout the Developer's Guide there are some general concepts and terminology used that are essential to understanding how SocketTools works. Each of these concepts is explored in detail, however a general, broad overview can also be useful when you are just getting started.

Protocols

A protocol, in terms of how the word is used in SocketTools, refers to the rules for how programs communicate with one another over a network. There are low level networking protocols such as TCP and UDP, as well as high level application protocols like FTP and HTTP. It can be helpful to think of a protocol as a sort of language; for two programs to communicate with each other, they must agree upon a protocol and understand how it is implemented.

Connections

The process of establishing a connection enables one program to communicate with another. Connection requests are made by client applications, and accepted by server applications. When the server accepts the connection request, the connection is completed. When you use the Connect function to successfully establish a connection to a server, a client session is created. SocketTools uses handles to reference specific sessions, and an application can create multiple client/server sessions if necessary.

Sessions

A session refers to an active connection between a client and server program. This term is typically used interchangeably with connection; however in some cases a single session may involve multiple network connections. For example, the File Transfer Protocol library establishes one connection, called the command channel, when the client initially connects to the server. However, when a file is being uploaded or downloaded, a second connection called the data channel is created just for that transfer. When the transfer completes, the second connection is terminated while the original command channel connection remains active. Even though there are multiple connections being made, SocketTools considers it to be a single client session. An active session is referenced by the handle which the Connect function returns to your program. When the session is no longer needed, the library's Disconnect function will terminate the connection to the server and release the resources allocated for that session. After that point, the handle is no longer valid and cannot be used in subsequent function calls.

Authentication

Many servers require that clients authenticate themselves by providing user names and passwords. Different application protocols implement several different types of authentication, and some protocols may support more than one authentication method. The SocketTools API provides one of two general types of authentication functions, depending on the protocol. For protocols which require the client to authenticate itself, the libraries will provide a Login function. Examples of this are **FtpLogin** and **ImapLogin**. For protocols where authentication is optional, the libraries will provide an Authenticate function. Examples of this are **HttpAuthenticate** and **SmtplibAuthenticate**. Refer to the technical reference for the specific protocol to determine if authentication is required.

Events

Developers who use visual programming languages like Visual Basic will find the concept of events and event handling to be very familiar. In general terms, the SocketTools documentation uses "event" to refer to a mechanism where the library notifies the client that an operation has completed, some action has taken place or a change in status has occurred. SocketTools implements events by posting user-defined messages to the application and/or invoking callback functions that have been registered by the client. Events can be handled by the client either by processing the messages in the application's message queue, or by implementing callback functions and registering those functions with the library. One example of an event is a connection event, which is generated whenever an asynchronous network connection is completed by the client. Another example is a progress event, which is generated periodically by the library to inform the client of its progress as it sends or receives data. To determine what events are available in a specific library, refer to the documentation for its ***RegisterEvent*** function. More specific information about event handling is provided later in this guide.

Application Design

The SocketTools API is designed to be flexible enough to address the needs of developers who have very basic needs, as well as those who have more complex requirements. As a result, the functions for a library can be broken down into two general categories: a high level interface to perform common tasks, and a lower level interface which provides more control at the expense of being somewhat more complicated and requiring more coding. For example, consider the Hypertext Transfer Protocol (HTTP) library which has a variety of high level functions such as **HttpGetFile**, **HttpPostData** and so on. Using these functions, your application can perform the most common tasks for that protocol with a minimum of coding. You don't need to even understand the basics of how the protocol works, or what the library is doing. The high level functions allow you to program against the API as though it is a "black box", where you can provide the input and process the output without concerning yourself with the details of what's going on behind the scenes.

However, in some cases it's necessary for an application to have more direct control over how the library operates or to take advantage of features that aren't explicitly supported by one of the higher level APIs. As an example, the HTTP library also has functions like **HttpCommand** which enable you to send custom commands to a web server. Normally, for operations like retrieving a file or posting data to a script, this isn't necessary. But if your application needs to use WebDAV, a set of extensions to the HTTP protocol to support distributed web authoring, then the lower level functions like **HttpCommand** enable you to do this.

If you are generally new to Internet programming or are just getting started with the SocketTools Library Edition, we generally recommend that you begin familiarizing yourself with the higher level functions using a basic synchronous (blocking) connection in a single-threaded application. Once you become more familiar with how the library works, then you can move on to more complex applications which leverage the lower level API functions, taking advantage of multithreading, asynchronous networking connections and so on.

One of the common pitfalls that developers can encounter with a large toolkit like SocketTools is the inclination to over-design the application from the start, and then become frustrated because they don't yet have a clear picture of how all the pieces fit together. Start out with a basic design and then as you become more familiar with how the SocketTools libraries work, expand on it. Developers who are used to working with the Windows API will find themselves right at home, but even if you are new to Windows programming, you'll find that developing applications with SocketTools will soon become second nature.

Program

Applications which use the SocketTools libraries will tend to have a similar structure, regardless of the specific protocol or programming language. While the details vary based on the library being used, the implementation can be broken down into several general steps:

- Initializing the library
- Connecting to the server
- Authenticating the client
- Performing one or more operations
- Disconnecting from the server
- Uninitializing the library

Initialization prepares the library to be used by your program, and is the first step that must be performed before you can use any other functions. Next, a connection is established with the server using the information provided by your program. For example, most of the connection functions require that you provide a host name, port number, a timeout period for synchronous operations and any additional options.

When the connection has completed, you will be given a handle to reference that client session; most of the SocketTools API require that you provide the function with a handle to identify the client session.

If the protocol requires that you authenticate the client in order to use the service, your application needs to provide this information. Once the client has been authenticated, it can then perform one or more operations, such as downloading a file, sending an email message and so on.

After you have finished, you disconnect from the server. Finally, before your program terminates, you uninitialize the library which causes it to perform any necessary housekeeping prior to releasing any system resources which were allocated on behalf of your program.

Library Initialization

When you begin developing your application using one of the SocketTools libraries, the first thing that you must do is initialize the library. This is done by calling the **Initialize** function for that library in your application's main thread. For example, the File Transfer Protocol library has a function named **FtpInitialize**, the Hypertext Transfer Protocol library has a function named **HttpInitialize** and so on. The one exception to this is the File Encoding library, which does not require initialization.

The initialization function serves two purposes. It loads the Windows networking libraries required to establish a connection and it validates the runtime license key that you provide. The runtime license key is a string of characters which identifies your license to use and redistribute the SocketTools libraries. It is unique to your product serial number and must be used when redistributing your application to an end-user.

Developers who are evaluating SocketTools will not have a runtime license key and must pass an empty string or a null pointer. This will enable the library to load on the development system during the evaluation period, but will prevent the library from being redistributed to an end-user until a license has been purchased.

If you install the product with a serial number, the runtime license key will be automatically created for you during the installation process. If you have installed an evaluation copy of SocketTools and then purchased a license, the license key can be created using the License Manager utility that was included with SocketTools. Simply select the **License | Header File** menu option and select the programming language that you are using. If your language is not listed, select Text File, which will create a simple text file with your license key.

The runtime license key is normally stored in the Include folder where you installed SocketTools and is defined in a file named "csrtkey11" which can be included with your application. For example, C/C++ programmers would use the csrtkey11.h header file while Visual Basic programmers would use the csrtkey11.bas module. The C++ header file would look something like this:

```
//
// SocketTools 11
// Copyright 2025 Catalyst Development Corporation
// All rights reserved
//
// This file is licensed to you pursuant to the terms of the
// product license agreement included with the original software
// and is protected by copyright law and international treaties.

#ifndef _INCLUDE_CSRTKEY8_H
#define _INCLUDE_CSRTKEY8_H

#ifndef UNICODE
#define CSTOOLS11_LICENSE_KEY ((LPCSTR)NULL)
#else
#define CSTOOLS11_LICENSE_KEY ((LPCWSTR)NULL)
#endif

#endif /* _INCLUDE_CSRTKEY8_H */
```

The macro CSTOOLS11_LICENSE_KEY specifies your runtime license key and this is what you would pass as the first argument to the initialization function. For example, here is how a C program would initialize the File Transfer Protocol library:

```
BOOL bInitialized;
bInitialized = FtpInitialize(CSTOOLS11_LICENSE_KEY, NULL);

if (!bInitialized)
{
    TCHAR szError[256];
```

```

    DWORD dwError;
    dwError = FtpGetLastError();
    FtpGetErrorString(dwError, szError, 256);
    MessageBox(NULL, szError, NULL, MB_OK|MB_TASKMODAL);
    return;
}

```

Note that in this case, the key is defined as NULL, which means that a runtime license key has not been created yet. The FtpInitialize function would succeed when the program was executed on the development system where the evaluation copy of SocketTools was installed, but would fail on another system. When a license is purchased and the runtime license key is generated, the csrkey11.h header file would be replaced with the actual key value. After re-compiling your program, you would be able to redistribute the application to other systems.

C++ programmers who are using the class wrappers are not required to explicitly initialize the libraries because this is done automatically in the class constructor. Review the cstools11.h file which defines all of the SocketTools classes to see how the constructor initializes the class.

For another example of how you can initialize the libraries, consider the Visual Basic module csrkey11.bas which defines the runtime license key:

```

'
' SocketTools 11 Build 2218
' Copyright 2025 Catalyst Development Corporation
' All rights reserved
'
' This file is licensed to you pursuant to the terms of the
' product license agreement included with the original software
' and is protected by copyright law and international treaties.
'

Public Const CSTOOLS11_LICENSE_KEY As String = ""

```

This is similar to the C/C++ header file and could either be included with your Visual Basic application or you could simply copy the string into your application. The equivalent to the C code listed above would look like this:

```

Dim bInitialized As Long
bInitialized = FtpInitialize(CSTOOLS11_LICENSE_KEY, 0)

If bInitialized = 0 Then
    Dim strError As String * 256
    Dim dwError As Long
    Dim nLength As Long
    dwError = FtpGetLastError()
    nLength = FtpGetErrorString(dwError, strError, 256)
    MsgBox Left(strError, nLength)
    Exit Sub
End If

```

In both examples, if the **FtpInitialize** function fails by returning a value of 0 (False), the program displays a message box to the user that explains the error and then exits.

An application is only required to call a library's initialization function once, but it must be called for each library that is used. If both the File Transfer Protocol and Hypertext Transfer Protocol libraries were being used in the same application, it would be required to call both **FtpInitialize** and **HttpInitialize** at the beginning of the program.

It is safe to call the initialization function more than once, but for each time that it is called, you must call the **Uninitialize** function for that library before your program terminates. For example, if you called **FtpInitialize** at the beginning of your program, you must call **FtpUninitialize** before your program ends. The **Uninitialize**

function performs any necessary housekeeping operations, such as returning memory allocated for the library back to the operating system. If there are any open connections at the time that the Uninitialize function is called, they will be aborted. After the library has been uninitialized, you must call the initialization function again in order to use any of the library's other functions.

Synchronous and Asynchronous Sockets

One of the first issues that you'll encounter when developing your application is the difference between synchronous (blocking) and asynchronous (non-blocking) connections. Whenever you perform some operation on a socket, it may not be able to complete immediately and return control back to your program. For example, a read on a socket cannot complete until some data has been sent by the server. If there is no data waiting to be read, one of two things can happen: the function can wait until some data has been written on the socket, or it can return immediately with an error that indicates that there is no data to be read.

The first case is called a synchronous or blocking socket. In other words, the program is "blocked" until the request for data has been satisfied. When the server does write some data on the socket, the read operation will complete and execution of the program will resume. The second case is called an asynchronous or non-blocking socket, and requires that the application recognize the error condition and handle the situation appropriately.

Programs that use asynchronous sockets typically use one of two methods when sending and receiving data. The first method is called polling and the program periodically attempts to read or write data from the socket, typically using a timer. The second method is to use what is called asynchronous event notification. This means that the program is notified whenever a socket event takes place, and in turn can respond to that event. For example, if the remote program writes some data to the socket, an event is generated so that program knows it can read the data from the socket at that point. Events can be in the form of Windows messages posted to the application's message queue, or as callback functions.

Synchronous Sockets

For historical reasons, the default behavior is for sockets to function synchronously and not return until the operation has completed. However, blocking sockets in Windows can introduce some special problems in single-threaded applications. To prevent the program from becoming non-responsive, the blocking function will enter what is called a "message loop" where it continues to process messages sent to it by Windows and other applications. Because messages are being processed, this means that the program can be re-entered at a different point with the blocked operation parked on the program's stack. For example, consider a program that attempts to read some data from the socket when a button is pressed. Because no data has been written yet, it blocks and the program goes into a message loop. The user then presses a different button, which causes code to be executed, which in turn attempts to read data from the socket, and so on.

To resolve the general problems with blocking sockets, the Windows Sockets standard states that there may only be one outstanding blocked call per thread of execution. This means that applications that are re-entered (as in the example above) will encounter errors whenever they try to take some action while a blocking function is already in progress. If the language supports the creation of threads, it is strongly recommended that the program create worker threads to perform any socket I/O.

There are significant advantages to using blocking sockets. In most cases, the application design and implementation is simpler, and raw throughput (the rate at which data is sent and received) is generally higher with blocking sockets because it does not have to go through an event mechanism to notify the application of a change in status. If you are using a programming language that supports multithreading, then the use of synchronous sockets is typically the best choice. However, if you are using an older language that does not provide support for multithreading, such as Visual Basic 6.0, and your program needs to establish multiple simultaneous connections, then an asynchronous, event-driven design is more appropriate.

Asynchronous Sockets

SocketTools facilitates the use of asynchronous sockets by generating events when appropriate. For example, an event occurs whenever the server writes on the socket, which tells your application that there is data waiting to be read.

In general, the use asynchronous sockets is preferred when you have a single-threaded application that must establish multiple, simultaneous connections with a server. In that situation, the use of non-blocking sockets avoids the restriction that prevents more than one outstanding socket operation in the thread and can enable the program to remain more responsive to the user. Practically speaking, there are few languages today that do not support multithreading, so this limitation tends to apply more to the legacy languages such as Visual Basic 6.0.

Best Practices

If your programming language of choice does support multithreading, it is recommended that you create worker threads to manage the sockets in your program. This leaves the main thread responsible for handling the user interface, and the worker threads can handle the network communications. There are some significant advantages to this approach:

- The networking code is generally isolated from the user interface, only requiring that the main UI thread be notified of the progress of the operation. For example, updating a progress bar control as the contents of a file is being downloaded. This tends to minimize any clutter in the UI code and creates a clear separation of functionality that will make the program easier to modify and maintain.
- Isolating the networking code in a worker thread ensures that there are no conflicts between other threads, including the main UI thread. Each thread effectively owns the sockets that it creates, and those sockets can be used independently of one another without concern about potential conflicts.
- Code written using synchronous sockets is typically easier to update, maintain and debug. The coding style lends itself to a more straight forward, top-down structure and logical errors are usually easier to find than with code written using asynchronous sockets.
- There is less overhead associated with synchronous sockets because no event mechanism is used, and handlers don't have to be implemented in callback functions. Event notifications that post messages to hidden window have to be processed through the message queue which is typically shared by the UI thread.
- Polling an asynchronous socket can cause spikes in CPU utilization and is generally not recommended. Applications which attempt to simulate blocking sockets by creating an asynchronous socket and then polling it can negatively impact the performance of the application, and in some cases the overall system.

In summary, there are three general approaches that can be taken when building an application with regard to blocking or non-blocking sockets:

- Use a synchronous (blocking) socket. In this mode, the program will not resume execution until the socket operation has completed. In a single-threaded application, blocking socket operations can cause code to be re-entered at a different point, leading to complex interactions (and difficult debugging) if there are multiple active connections in use by the application. If the programming language supports multithreading, it is recommended that each connection be isolated within its own worker thread.
- Use an asynchronous (non-blocking) socket, which allows your application to respond to events. For example, when the server writes data to the socket, an event is generated. Your application can respond by reading the data from the socket, and perhaps send some data back, depending on the context of the data received. The code required for managing asynchronous sockets can be more complex, however it is the best solution for single-threaded applications that must establish simultaneous connections.
- Use a combination of synchronous and asynchronous socket operations. The ability to switch between blocking and non-blocking modes "on the fly" provides a powerful and convenient way to perform socket operations under some circumstances. However, switching between blocking and non-blocking mode can make the application more complex and difficult to debug. It is important to note that the

warning regarding blocking sockets also applies here.

If you decide to use asynchronous sockets in your application, it's important to keep in mind that you must check the return value from every read and write operation. It is possible that you may not be able to send or receive all of the data specified at that time. Frequently, developers encounter problems when they write a program that assumes a given number of bytes can always be written to or read from the socket. In many cases, the program works as expected when developed and tested on a local area network, but fails unpredictably when the program is released to a user that has a slower network connection (such as a serial dial-up connection to the Internet). By always checking the return values of these operations, you insure that your program will work correctly, regardless of the speed or configuration of the network.

Secure Connections

The SocketTools Library Edition supports the ability to create secure connections using the Transport Layer Security (TLS) and Secure Shell (SSH) protocols. For those protocols which support them, enabling a secure connection is typically as simple as specifying an additional option when the Connect function is called. In some cases, certain protocols have additional options that control how the secure session is established.

Secure TLS connections may either be implicit or explicit, depending on the protocol. An implicit connection is one where the client and server begin negotiating the security options as soon as the connection is established. In most cases, a server which accepts secure implicit connections listens on a port number that is different from the default port it uses for standard, non-secure connections. An example of this is the Hypertext Transfer Protocol (HTTP) which accepts standard connections on port 80 and secure connections on port 443. When a client connects to port 443, the server automatically assumes that the client wants a secure connection.

On the other hand, an explicit connection requires that the client explicitly specify to the server that it wants a secure connection. Typically this is done by the client sending a command to the server that causes the server to begin negotiating with the client to establish a secure session. An example of this is the File Transfer Protocol, where the client can use the AUTH command to tell the server that it wants a secure connection. Servers may also support both explicit and implicit secure connections, based on which port the client connects to. SocketTools supports both implicit and explicit secure connections, and this is also controlled by the options specified to the library's Connect function.

In addition to establishing a secure connection, the client may be required to provide additional authentication information to the server in form a client certificate. A secure server may require that the client provide a certificate in addition to or instead of a username and password. To support this, your application must create the security credentials for the client and pass those to the Connect function. For more information, refer to the **SECURITYCREDENTIALS** structure in the Technical Reference. Additional information about secure connections and certificates is also available in the Developer's Guide.

Network Input/Output

Each of the SocketTools networking libraries provides functions for sending and/or receiving data from a server. At the lowest level, this is done by calling the Write function for sending data and the Read function for receiving data. For example, the File Transfer Protocol library has the functions **FtpWrite** and **FtpRead**. In most cases, these functions exchange data as a stream of bytes without any regard for the actual content. For developers who are using Unicode, it is important to note that there are no Unicode versions of these functions. If the data being sent or received is textual, it is your program's responsibility to convert it into an appropriate format, typically using the **MultiByteToWideChar** and **WideCharToMultiByte** functions that are part of the standard Windows API.

When working at this very low level, it is important to understand how data is exchanged over the network. Many developers are inclined to think of the data that is sent or received in terms of discrete blocks, or packets. The expectation is that if they send a certain number of bytes of data in a single write, the server will receive that number of bytes in a single read. However, this is not how TCP works, and by extension, not how the SocketTools libraries work with regards to this kind of low level network I/O. The Transmission Control Protocol (TCP) is called a stream-oriented protocol because data is exchanged between the client and server as a stream of bytes. While TCP will guarantee that the data will arrive intact, with the bytes received in the same order that they were written, there is no guarantee that the amount of data received in a single read operation on the socket will match the amount of data sent by the remote host.

For example, consider a server that sends data to a client in four separate operations, each containing 1024 bytes of data. While it is convenient to think of these as discrete blocks of data, TCP considers it to be a stream of 4096 bytes. The client may receive that data in a single read on the socket, returning all 4096 bytes. Alternatively, it may read the socket, and only receive the first 1460 bytes; subsequent reads may return another 1460 bytes, followed by the remaining 1176 bytes. Applications which make assumptions about the amount of data they can read or write in a single operation may work in some environments, such as on a local network, but fail on slower connections.

A general rule to use when designing an application using TCP is to consider how the program would handle the situation where reading *n* bytes of data only returns a single byte. If the application can correctly handle this kind of extreme case, then it should function correctly even under adverse network conditions.

In some situations it may be desirable to design the application to exchange information as discrete messages or blocks of data. While this isn't directly supported by TCP, it can be implemented on top of the data stream. There are several methods that can be used to accomplish this, depending on the requirements of the application:

1. Exchange the data as fixed length structures. This is the simplest approach, and has very little or no overhead. The client and server can either use predefined values, or negotiate the size of the data structures when the connection is established.
2. Prefix variable-length data structures with the number of bytes being sent. The length value could be expressed either as a native integer value, or as a fixed-length string that is converted to a numeric value by the application. This allows the receiver to read this fixed length value, and then use that value to determine how many additional bytes must be read to obtain the complete message or data structure.
3. Prefix the data with a unique byte or byte sequence that would normally not be found in the data stream. This would be followed by the data itself, with a complete message received when another unique byte sequence is encountered. Alternatively, a unique byte sequence could be used to terminate a message. This is the approach that many Internet application protocols use, such as FTP, SMTP and POP3. Commands are sent as one or more printable characters,

terminated with a carriage-return (CR) and linefeed (LF) byte sequence that tells the server that a complete command has been received.

4. A combination of the above methods, using unique byte sequences, the message length and even additional information such as a CRC-32 checksum or MD5 hash to validate the integrity of the data. This would effectively create an "envelope" around the data being exchanged, and additional checks could be made to ensure that the data has been received and processed correctly.

Regardless of the method used, for best performance it is recommended that the application buffer the data received and then process the data out of that buffer. When using asynchronous (non-blocking) sockets, the application should read all of the data available on the socket, typically in a loop which adds the data to the buffer and exiting the loop when there is no more data available at that time.

It is important to keep in mind that all of this is only required if you decide to use the lower level APIs in the SocketTools libraries. The higher level APIs automatically handle the lower level network I/O for you. For example, the **FtpGetData** function will retrieve a file from the server and return the entire contents to your application in a single function call. When using the high level APIs, the details of how the data is read and processed is handled by the library and no additional coding is required on your part.

Event Handling

In SocketTools, event notification provides a mechanism for the library to inform the application of a change in the status of the current session. Events are generally divided into two general categories, asynchronous network events and status events.

Asynchronous network events occur when a non-blocking connection is established and a network event occurs, such as a connection completing or data arriving from the server. Status events are used to indicate a change in status, such as a blocking operation being canceled or the progress of an operation such as a file transfer.

Asynchronous network events require that the program provide a handle to a window that will receive the event message and a user-defined message identifier that will be used to identify the event to the application. Typically the window is an invisible window created specifically for the purpose of processing events, however it can also be a visible window used by the application such as a form or dialog. If the window handle refers to a visible window, it is important to remember that if the window is destroyed, asynchronous event notification will automatically be disabled. In general it is recommended that the application use a private, invisible window if asynchronous network events are required. To enable event handling, each of the networking libraries has a function named **EnableEvents** which accepts a handle to a window and a unique message identified. There is also a **DisableEvents** function which will disable event handling. For example, the Hypertext Transfer Protocol library has functions called **HttpEnableEvents** and **HttpDisableEvents**. Note that if you initially establish an asynchronous connection, it is not necessary to explicitly call the **EnableEvents** function for the library since you will already have a non-blocking connection and events will be posted to the specified window.

In addition to posting event notifications to a window, it is also possible to register an event handler that will be called by the library whenever the event occurs. In this case, you would use the **RegisterEvent** function for the library, where you would specify the event that you wish to register, along with a user-defined parameter that will be passed to the callback function.

In some cases, it is desirable to suspend event handling for a session. To accomplish this, the libraries have a function called **FreezeEvents** which can be used to suspend and resume event handling. While events are frozen, network events will be queued rather than posted to the notification window. When event handling is resumed, those events will be fired and event handling will resume normally. It is recommended that applications freeze event handling when they are performing some action where it would not be desirable for the event handler to be executed. Examples of where this would be appropriate would be a modal dialog or a message box, where the user must respond before the application continues executing.

An important consideration when it comes to event handling is that all asynchronous network events are level triggered. This means that once an event is fired, it will not be fired again until some action is taken by the application to handle the event. This is most commonly found with events that are generated when the server sends data to your application, signaling to you that there is data available to be read. Even though the server may continue sending you more data, another event will not be generated until you read at least some of the data that has been sent to you. This is done to prevent the application from being flooded with event notifications. However, failure to handle an event can cause event notification to appear to stall. If you determine that you cannot handle an event at the time, you must freeze event handling. You can resume event notification when you are in a position to process events again.

Error Handling

Typically an error is indicated when a SocketTools function either returns a value of zero (false) or -1. When an error occurs in one of the libraries, the **GetLastError** function can be used to obtain the error code. The **GetLastError** function returns a unsigned 32-bit integer value that is unique to each thread in a given application. Each library also has it's own private function which will return the last error code for the current thread. For example, the File Transfer Protocol library has a function called **FtpGetLastError**. SocketTools error codes conform to the standard format used by Windows:

The **S** bitfield is used to refer to the severity of the error. A value of zero specifies success, while a value of one specifies an error condition.

The **R** bitfield is reserved for future use by Windows, and must be set to zero. Applications should not take any action based on the values of these two bits.

The **Facility** bitfield specifies which group of status codes the error belongs to. The SocketTools libraries use FACILITY_ITF, which is designated for use by third-party libraries.

The **Code** bitfield specifies the actual error code. This may correspond to a Windows Sockets error, or an error that is unique to the SocketTools libraries.

Each of the SocketTools error codes has a matching constant, defined in the header files or modules provided for your programming language. These constants should always be used for comparison against the value returned by the **GetLastError** function.

For each error code, there is a matching description of the error which can be used by the application. Applications may choose to use these error descriptions when displaying a message box to a user or for internal logging purposes. To retrieve the description of the error, the **FormatMessage** function can be used. Each library also has its own private function to return an error description which may be easier to use. For example, the File Transfer Protocol library has a function called **FtpGetErrorString**, the Hypertext Transfer Protocol library has a function called **HttpGetErrorString** and so on.

Debugging Facilities

All of the SocketTools networking libraries include a built-in facility for generating debugging output in the form of a log file that provides information about the internal functions that it is using and the data that is being exchanged between the client and server. This is commonly referred to in the documentation as generating a trace log or enabling function logging.

To provide logging functionality for your application, you must redistribute the `cstrcv11.dll` library along with those SocketTools libraries you are using in your program. The **cstrcv11.dll** library is what performs the actual logging and must be in a directory where it can be loaded by your application. It is recommended that you either install it in the Windows system directory or the directory where your application is installed. Note that this is a standard Windows dynamic link library and it does not need to be registered.

To create a trace log, your application must then call the **EnableTrace** function in the library. For example, if you were using the Simple Mail Transfer Protocol library, you would call the function **SmtpEnableTrace**. This function requires two arguments: the name of a file that the trace log data will be written to and a numeric value which specifies the level of the trace. The default level, zero, specifies that general information about the function calls being made will be logged. The most detailed logging is provided by specifying a level of four. In that case, all data exchanged between your application and the server is logged. This provides the most information, however it also generates the largest log files. To disable logging, use the **DisableTrace** function for the library, such as **SmtpDisableTrace**.

There are two important things that you need to consider when enabling trace logging. The first is that the log file is always appended to, never overwritten by the library. This means that the files can grow to be very large, particularly with trace that includes all of the data sent and received by your application. You can use the standard file I/O functions in your language to manage the log file or even write your own data out to the file. Each time the file is written to, SocketTools will open the file, append the logging data and then close the file. The libraries will never keep the file open between operations. This is important because if your application terminates abnormally, it ensures all of the logging data has been written and there are no open file handles being held by one of the libraries. However, this does incur additional overhead and can impact the performance of your application. When possible, it is recommended that you enable logging around the functions that you feel may be part of the problem you're trying to resolve, and then disable logging when it is no longer required. Simply enabling logging at the beginning of your application can result in unnecessarily large log files.

If your application uses multiple SocketTools libraries, it is only necessary to enable logging in one of them. Once enabled, all SocketTools network operations in the current thread will be logged, regardless of which library was used to enable logging.

Language Support

The SocketTools Library Edition can be used with a wide variety of programming languages and software development tools for Windows. The majority of the library functions use simple data types such as 16-bit and 32-bit integers, and null character terminated strings. To determine if your development language is capable of using the Library Edition, it should support all of the following features:

- It needs the ability to load a dynamic-link library (DLL) and call exported functions from that library. In some cases, as with C or C++, you can use an import library instead of dynamically loading the library. This allows you to link your program just as you would a standard function library. If the language does not support the use of import libraries, it must provide a mechanism for declaring a function and specifying the arguments that will be passed to it.
- Languages must call the SocketTools functions using the **stdcall** calling convention. Parameters are pushed on to the stack in reverse order (from right to left), and the called function is responsible for clearing the stack. Note that this is different from the standard C/C++ calling convention in which the stack is cleared by the calling function, and from the Pascal calling convention in which arguments are pushed on the stack left to right.
- The language must support basic integer data types, including 16-bit, 32-bit and 64-bit integers. The language must also support a string data type that is represented as an array of bytes, terminated by a null character (a character with the ASCII value of zero). If a different native string type is used, the language must provide a means to convert between the native string format and a null-terminated byte array.
- The language must support passing function parameters by value and by reference. When a variable is "passed by value", a copy of its value is passed to the function on the stack. However, when a variable is "passed by reference", the memory address of the variable (typically called a pointer) is passed to the function. In most cases, the functions in the SocketTools library expect integer data to be passed by value, while string and data structures are passed by reference.
- In addition to passing a variable by reference to a function, the language must provide the ability to allocate a block of memory of arbitrary size and be able to pass its address to a function. For example, in C there are the malloc() and free() functions, and in Visual Basic there are the Dim and ReDim statements.
- The language must support calling functions which do not return a value. For example, in C and C++, such functions are declared as void. In Visual Basic, a function which does not return a value is declared as Sub (a subroutine).

Although not required, it is recommended that the language also support the ability to create user-defined data structures. For example, in C and C++, the struct keyword is used to define a data structure. In Visual Basic, the Type statement is used to create user-defined data structures.

Microsoft Visual C++, Visual C#, Visual Basic.NET, Visual Basic 6.0, C++ Builder and Delphi are all examples of languages which can use the SocketTools Library Edition. If your programming language is capable of calling native Windows API functions, then you should be able to use SocketTools. Consult your language technical reference for additional information about how to call functions exported from a standard Windows dynamic link library.

Data Types

Because various languages handle data types in different ways, the SocketTools libraries have been designed to primarily use basic data types such as integers and strings. The following is a list of numeric data types that are used, along with their C++, C# and Visual Basic equivalents.

Description	Size	Range	Win32 API	C++	C#	VB 6	VB.NET
Byte	1 byte	0 to 255	BYTE	uint8_t	byte	Byte	Byte
Boolean	4 bytes	0 is False, 1 or -1 is True	BOOL	int32_t	int	Long	Integer
Handle	4 bytes	0 to 4,294,967,295	HCLIENT	void *	IntPtr	Long	IntPtr
Integer	4 bytes	-2,147,483,648 to 2,147,483,647	INT	int32_t	int	Long	Integer
Integer	4 bytes	0 to 4,294,967,295	UINT	uint32_t	uint	Long	UInteger
Short Integer	2 bytes	-32,768 to 32,767	SHORT	int16_t	short	Integer	Short
Short Integer	2 bytes	0 to 65,535	WORD	uint16_t	ushort	Integer	UShort
Long Integer (32-bit)	4 bytes	-2,147,483,648 to 2,147,483,647	LONG	int32_t	int	Long	Integer
Long Integer (32-bit)	4 bytes	0 to 4,294,967,295	DWORD	uint32_t	uint	Long	UInteger
Long Integer (64-bit)	8 bytes	-9,223,372,036,854,775,808 to 9,223,372,036,854,775,807	LONGLONG	int64_t	long	N/A	Long
Long Integer (64-bit)	8 bytes	0 to 18,446,744,073,709,551,615	ULONGLONG	uint64_t	ulong	N/A	ULong

One problem that is frequently encountered when converting function definitions from C or C++ to other languages is the size of the integer data type. For example, default integer size for Visual Basic 6 is 16-bits on 32-bit platforms. However, in Visual Basic .NET, as well as languages like Visual C++, the default integer size is 32-bits. Also, some languages do not support unsigned integer types. In this case, as with Visual Basic, the signed type should be used instead.

Visual Basic 6.0 does not have a native 64-bit integer type, however a 64-bit value can be represented with a structure. Most SocketTools APIs which use 64-bit integers either represent them as LARGE_INTEGER or LONGLONG values. In Visual Basic, the structure would look like this:

```
Public Type LARGE_INTEGER
    LoPart As Long
    HiPart As Long
End Type
```

This would contain the lower 32-bit and upper 32-bit values of the 64-bit integer. This same structure is also used in various Windows API functions. The same approach can also be used with other languages which do not natively support 64-bit integers, but are capable of passing small structures by value as arguments to functions.

Boolean Data

Boolean parameters present a special problem for two reasons. Firstly, the data types used to represent Boolean values frequently vary between languages. Secondly, different languages represent the values "true" and "false" differently. Boolean parameters (declared as **BOOL** in the function prototypes) should always be passed as 32-bit signed integers.

It is important to note that in C++ the **bool** type is an unsigned 8-bit integer and is different than **BOOL**, which is a signed 32-bit integer used with SocketTools functions. The .NET languages also have **System.Boolean** which is not a numeric value, but rather a structure type where the only values are true or false. The SocketTools function definitions for Visual Basic and C# use marshaling to change the numeric values used by the SocketTools API to native .NET boolean types.

If you are passing a Boolean parameter to a function, then "false" should be represented by a value of zero and "true" as a non-zero value, typically a value of one. When writing code that checks a Boolean flag, or tests a Boolean return value from a function, it is recommended that you test against a value of zero. For example, consider the following code in Visual Basic 6.0:

```
Dim bConnected As Long
bConnected = InetIsConnected(hSocket)
If bConnected = True Then
    ' The socket is connected to a server
Else
    ' The socket is not connected, or the socket handle
    ' may be invalid; call InetGetLastError to check the
    ' error code
End If
```

In this example, even if the function **InetIsConnected** was successful, the program would always believe that it failed because of the explicit test against the value **True**. This is because the function returns a value of 1 to indicate success, but Visual Basic defines **True** as -1. Instead, the code should be written as:

```
Dim bConnected As Long
bConnected = InetIsConnected(hSocket)
If bConnected <> 0 Then
    ' The socket is connected to a server
Else
    ' The socket is not connected, or the socket handle
    ' may be invalid; call InetGetLastError to check the
    ' error code
End If
```

In summary, the rule of thumb for dealing with boolean parameters is that they should always be 32-bit integer values, and you should always compare the boolean against a value of zero, never against a predefined constant like **True**.

String Data

String parameters can also present a challenge when calling functions from languages other than C and C++. Different languages tend to have different internal representations of how string data is stored. The convention used by the SocketTools libraries is that a string is an array of characters, terminated by a null character (a character with an ASCII value of zero). The length of the string is not stored in the string data itself, and by definition, a string cannot contain embedded nulls.

The size of a character depends on whether the ANSI or Unicode version of a function is being called. SocketTools includes support for both types of strings and which you use generally depends on how you have your project configured. For example, consider the function **InetReadLine** which reads a line of text from a socket and returns

it in a string buffer. There are actually two versions of this function, **InetReadLineA** which uses an 8-bit ANSI string buffer, and **InetReadLineW** which accepts a 16-bit Unicode string buffer.

Depending on the language, **InetReadLine** may be a macro which expands to the appropriate version based on the project. This is the case for C/C++ projects, where which version of a function is called is determined by the project settings and whether or not the UNICODE macro is defined. For other languages, one version of the function will always be used. For example, with Visual Basic 6.0 only the ANSI versions of the functions are defined, while for C# and Visual Basic .NET only the Unicode version of functions are declared, with marshaling used to convert them to the native System.String type.

To use functions which require string parameters, the language must be capable of converting between its native string data type and the null-terminated character array expected by the SocketTools functions. For example, Object Pascal provides the StrPCopy function. Note that Visual Basic provides implicit conversion between its native string type and null-terminated strings when a string is passed by value (ByVal) instead of by reference.

If you are unsure of how your language handles null-terminated strings, we recommend that you review the language's technical reference for information on how to call native Windows API functions. Since the Windows API also uses null-terminated strings, that same information can be used to determine how to call functions in the SocketTools libraries.

Unicode

Unicode is a multi-language character set designed to encompass virtually all of the characters used with computers today. Unicode characters are represented by a 16-bit value on Windows, and differ from other character sets in two important ways. First, unlike the traditional single-byte (ANSI) character sets, Unicode is capable of representing significantly more characters in a variety of languages. Second, unlike multi-byte character sets (where some characters may be one byte in length, while others may be two, three or four bytes), on Windows the Unicode characters are fixed-width, which can make them easier to work with.

The SocketTools libraries support both the ANSI and Unicode character sets by providing two versions of each function that either expects a string as an argument (including those functions which pass structures that contain strings) or returns the address of a string. The functions which use multi-byte strings have a suffix of "A" (ANSI), while the functions which use Unicode strings have a suffix of "W" (wide). No suffix is used with functions which expect binary (non-textual) data or only use numeric parameters and return numeric values.

For example, consider the **InetGetLocalName** function mentioned in the previous section. If you looked at the list of exported functions in the library, you would see two functions exported, **InetGetLocalNameA** and **InetGetLocalNameW**. In C and C++, which function is called actually depends on how the application is being built. That is, if your application is built to use Unicode (in other words, the UNICODE macro is defined and you are linking with Unicode versions of the standard libraries), then the **InetGetLocalNameW** function will be used instead of the **InetGetLocalNameA**. In other languages, you may have to explicitly declare which version of the function you wish to use. In Visual Basic, for example, the Alias keyword must be used with the function declaration to specify the correct name.

Automatic Encoding

When building a project that is configured to use the Unicode character set, SocketTools will automatically convert strings to UTF-8 encoded text before transmitting that data over the network. This conversion only occurs with string types, and will not be performed on byte arrays or other types of data that is not represented as a null terminated string value.

Converting strings to UTF-8 encoding ensures textual data is sent and received in a uniform way that is not affected by the local system's localization and language settings. Virtually all modern servers on the Internet today expect text to be exchanged using UTF-8 encoding, and because ASCII characters are considered a subset of UTF-8, they are not subject to encoding.

Earlier versions of SocketTools always performed Unicode string conversions using the default system code page, rather than using UTF-8 encoding. This change will not typically affect most applications; however, if you are using Unicode strings, it is important to keep in mind that this conversion to UTF-8 can change how data is exchanged over the network. If you want to prevent this automatic UTF-8 encoding, you can perform the preferred conversion in your code (for example, using the **WideCharToMultiByte** function) and then explicitly call the ANSI version of the SocketTools function, rather than the Unicode version.

The Encoding and Compression library includes helper functions that can simplify the process of performing UTF-8 encoding and decoding. The **IsUnicodeText** function will analyze a string buffer to determine if it contains valid Unicode text. The **UnicodeDecodeText** and **UnicodeEncodeText** functions can be used to perform conversions between UTF-8 encoded text, multi-byte and Unicode strings.

Strings and Byte Arrays

Some SocketTools functions require you to use byte arrays instead of strings, regardless of the character set your project uses. This can create problems when reading and writing Unicode string data. For example, consider the **InetRead** and **InetWrite** functions which are used to read and write data on a socket. Because character strings and byte arrays are essentially identical when using the ANSI character set, a C/C++ programmer may try to write code such as this:

```
LPTSTR lpszData = _T("This is a test, this is only a test");
INT cchData = lstrlen(lpszData);
INT nResult;
```

```
nResult = InetWrite(hSocket, lpszData, cchData);
```

This would work as expected until you change your project to use the Unicode character set. The problem is that the Unicode string is no longer an array of 8-bit bytes, but is now an array of 16-bit integers. The Unicode string must be converted to a byte array before passing it to the **InetWrite** function. One way to do this is to use the **WideCharToMultiByte** function:

```
LPTSTR lpszData _T("This is a test, this is only a test");
INT cchData = lstrlen(lpszData);
LPBYTE lpBuffer;
INT nResult;
```

```
#ifdef UNICODE
lpBuffer = (LPBYTE)_alloca((cchData + 1) * 4);

if (lpBuffer == NULL)
{
    // Unable to allocate memory
    return;
}

cchData = WideCharToMultiByte(CP_UTF8, 0,
                              (LPCWSTR)lpszData,
                              cchData,
                              (LPSTR)lpBuffer,
                              ((cchData + 1) * 4),
                              NULL, NULL);

if (cchData <= 0)
{
    // Unable to convert the Unicode string
    return;
}
#else
pBuffer = (LPBYTE)lpszData;
#endif

nResult = InetWrite(hSocket, lpBuffer, cchData);
```

Note that the type of characters being converted may also present a problem to the developer. In this example, the string is easily converted because it is composed only of characters that are part of the basic ASCII character set. In most cases it is recommended that you use CP_UTF8 to convert the text to UTF-8. When converting a string that contains international characters, such as accented vowels, the conversion using the system code page may result in unprintable characters. For additional information, check your programming language's technical reference for issues with regards to localization and the use of Unicode.

Microsoft Visual C++

The SocketTools Library Edition includes import libraries, header files and class wrappers which can be used with Microsoft Visual C++ 10 and later. If you are using Visual Studio 2010, you should have Service Pack 1 installed. If you are using Visual Studio 2012 or 2013, you should have Update 5 installed. If you are using Visual Studio 2015, you should have Update 3 installed. For Visual Studio 2017 and later, use the Visual Studio Installer to ensure that you have the latest updates installed.

To build an application using SocketTools with Visual C++, the first step is to make sure the compiler is configured correctly to specify the correct paths to the directories where the header files and import libraries are found. In Visual C++, this is done by selecting Tools | Options from the menu, and then selecting the Directories tab. In Visual Studio, this is done by selecting Tools | Options from the menu, then selecting the Projects folder and the VC++ Directories properties page. The path for the include files should be the Include folder, and the path for the library files should be the Lib folder, found where you installed SocketTools.

When you install SocketTools, an environment variable named **SocketTools11** will be created which provides the full path to the installation folder. In Visual Studio and other IDEs, you can typically reference this environment variable rather than hard-coding the path. For example, the include folder would be **\$(SocketTools11)\Include**. For compatibility with both 32-bit and 64-bit Windows platforms, SocketTools will be installed in the **C:\Program Files (x86)\SocketTools 11.0 Library Edition** folder on 64-bit Windows, and **C:\Program Files\SocketTools 11.0 Library Edition** on 32-bit Windows.

If you are programming in C or C++, you must include the header file **cstools11.h** in your program. This file contains all of the macro, type, structure and function prototype definitions used by the SocketTools libraries. This will also automatically include two other header files which are used by SocketTools. The **cserror11.h** header file defines all the error codes, and the **csrtkey11.h** header defines the runtime license key which is used to initialize the SocketTools libraries.

When you include the SocketTools header file, it will automatically include **windows.h** and several other standard Windows API header files. If you include the Windows header file before you include the SocketTools header, you will get an error indicating that you must include the SocketTools header file first. This is because the Windows header file will attempt to include the (now deprecated) **winsock.h** header by default. If possible, include the SocketTools header file first and there won't be a need to explicitly include the Windows header. Alternatively, you can define the macro **WIN32_LEAN_AND_MEAN** which tells the Windows header to only include other essential header files. Your application should never explicitly include either **winsock.h** or **winsock2.h** because those are automatically included by the SocketTools header.

If you are using Microsoft Foundation Classes (MFC) with your project, you will need to include **afx.h** before you include the SocketTools header file. Also make sure your project has explicitly defined the **_WIN32_WINNT** macro to indicate the minimum target platform for your project. If it is undefined, a warning will be issued and it will default to the highest operating system version supported by the Windows development kit you have installed.

A collection of classes which encapsulate the SocketTools API are also included as part of the standard header file. The SocketTools classes can be used with or without the Microsoft Foundation Classes (MFC), although certain functions are only available if MFC is used. The classes themselves are designed to be basic wrappers around the API and it is expected that most developers will use them as the base class for their own classes.

For Visual C++ programmers, there are special macros which are used in the **cstools11.h** header file which controls certain behavior:

CSTOOLS_NO_LIBRARIES

Visual C++ supports a pragma which can be used to automatically specify the names of libraries that the compiler should attempt to link with in order to resolve function calls. By default, it is not necessary to explicitly specify the names of the SocketTools import libraries to link to. However, if you wish to

explicitly link to specific import libraries, then define this macro prior to including the `cstools11.h` header file.

CSTOOLS_NO_NAMESPACE

When compiling a C++ application, the SocketTools functions are defined in a namespace called `SocketTools`. This prevents the possibility of conflicts with functions of the same name that may be used in other libraries. If you prefer the functions to be defined in the global namespace instead, then define this macro prior to including the `cstools11.h` header file.

CSTOOLS_NO_CLASSES

When compiling a C++ application, class wrappers for the SocketTools API are normally included with the function prototypes. Defining this macro prevents the C++ classes from being defined, limiting the application to using only the standard functions.

These macros are not normally defined, and in most cases they will not be needed. Please note that if for some reason you modify the header files directly, you should copy the changes to another file using a different name. Otherwise, when you install an update to the product, the **`cstools11.h`** and **`cserror11.h`** header files will be replaced and you will lose your modifications.

Microsoft Visual C#

The SocketTools Library Edition provides a C# module in the Include folder named `cstools11.cs` which can be included with your projects. This defines a namespace called `SocketTools` which contains classes for each of the libraries, as well as the constants and error codes. It also defines some standard Windows API functions which can be helpful when using some of the `SocketTools` functions.

String Arguments

Although the `SocketTools` libraries are unmanaged code, for the most part you won't have to be concerned about marshaling data. However, there are a few special considerations that programmers should be aware of when using the `SocketTools` API. The first deals with string buffers that are passed by reference and modified by the function. An example of this would be the **`HttpGetErrorString`** function, which is used to obtain a description of a specific error. In C/C++ you would allocate a character array and pass it to the function, such as:

```
TCHAR szError[256];
DWORD dwError;
INT nLength;

dwError = HttpGetLastError();
nLength = HttpGetErrorString(dwError, szError, 256);
MessageBox(NULL, szError, "Error", MB_OK | MB_ICONEXCLAMATION);
```

In C#, the `HttpGetErrorString` function declaration uses the **`StringBuilder`** class as the string argument. The equivalent code in C# would be:

```
StringBuilder strError = new StringBuilder(256);
uint dwError;
int nLength;

dwError = HttpGetLastError();
nLength = HttpGetErrorString(dwError, strError, 256);
MessageBox.Show(strError.ToString(), "Error",
    MessageBoxButtons.OK,
    MessageBoxIcon.Exclamation);
```

Make certain you use the **`System.Text`** namespace which defines the **`StringBuilder`** class. Also keep in mind that if you want to pass a **`StringBuilder`** variable to a function that expects a **`String`**, you should use the **`ToString`** method.

Byte Array Arguments

A number of `SocketTools` functions use byte arrays, either as an input argument to the function, or as an output argument which will contain data when the function returns. An example of this is the **`HttpGetData`** function, which will access a resource on the server and return the contents of that resource in a byte array passed to the function. For example, the following code in C++ would return the first 1024 bytes of the index page on a web server:

```
BYTE byteBuffer[1024];
DWORD dwLength;
INT nResult;

dwLength = sizeof(byteBuffer);
nResult = HttpGetData(hClient,
    "/index.html",
    byteBuffer,
    &dwLength,
    0);
```

If the function is successful, the `byteBuffer` array will contain the first 1024 bytes of the index page. In C#, the equivalent code would look like this:

```
byte[] byteBuffer = new byte[1024];
uint dwLength;
int nResult;

dwLength = (uint)byteBuffer.Length;
nResult = HttpGetData(hClient,
    "/index.html",
    byteBuffer,
    ref dwLength,
    0);
```

In C++, byte arrays can be used interchangeably with ANSI strings. However, in C# you will need to use the **System.Text.ASCIIEncoding** class to convert a byte array into a string. For example:

```
String strBuffer = (new ASCIIEncoding()).GetString(byteBuffer, 0, (int)dwLength);
```

This would convert the contents of the byte array into a `String`. Note that you should only do this if the data returned by the function is actually text. In this example, it is acceptable to do because the byte array contains the HTML text for the index page.

Global Memory Handles

In addition to using byte arrays, some `SocketTools` functions can use global memory handles (HGLOBALS) to exchange large amounts of data. Using the Windows API, global memory handles are allocated by the **GlobalAlloc** function, dereferenced by the **GlobalLock** function and released by the **GlobalFree** function. These handles can be used in C# by using the **System.Runtime.InteropServices** marshaling classes. There are also some helper functions defined in the `SocketTools.Win32` class which can be used to dereference and release global memory handles.

An application may choose to use a global memory handle instead of a pre-allocated buffer if the amount of data is very large, or the total amount of data that will be returned is unknown at the time the function is being called. Consider the call to the **HttpGetData** function used in the previous example. A pre-allocated buffer of 1024 bytes was passed to the function, and it copied up to that amount of data into the buffer. However, what if you wanted the complete page and did not know how large it was? You could attempt to determine the size of the page that was being requested using the **HttpGetFileSize** function, and then use that value to allocate a buffer. However, this incurs additional overhead and it is not always possible to get the size of a resource on a web server. Another alternative would be to simply allocate a very large buffer, but this could result in the application allocating large amounts of memory that it doesn't use and you would still run the risk that it wouldn't be large enough.

The solution for this problem is to use a global memory handle rather than a pre-allocated buffer. Instead of copying the data into a buffer, the function allocates a global memory handle and stores the contents in the memory referenced by that handle. When the function returns, it passes the handle back to the caller. The caller then dereferences the handle to access the memory, and releases the handle when it is no longer needed. Here is an example of how it would be used in C/C++:

```
HGLOBAL hgb1Buffer = NULL;
DWORD dwLength = 0;
INT nResult;

nResult = HttpGetData(hClient,
    "/index.html",
    &hgb1Buffer,
    &dwLength,
    0);
```

```

if (nResult != HTTP_ERROR)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}

```

Note that the global memory handle is initialized to NULL and the length argument is initialized to zero. This is important to do because this is how the function knows that it should be returning a global memory handle instead of copying data into a buffer. If you forget to initialize those arguments, the function will fail and may cause the application to terminate with a general protection fault.

The equivalent code in C# would look like this:

```

uint hgblBuffer = 0;
uint dwLength = 0;
int nResult;

nResult = HttpGetData(hClient,
                      "/index.html",
                      ref hgblBuffer,
                      ref dwLength,
                      0);

if (nResult != HTTP_ERROR)
{
    IntPtr lpBuffer = Win32.GlobalLock(hgblBuffer);
    String strBuffer = Marshal.PtrToStringAnsi(lpBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    Win32.GlobalUnlock(hgblBuffer);
    Win32.GlobalFree(hgblBuffer);
}

```

It is important to remember to unlock and release the global memory handle when you are no longer using it. Those handles are not managed by the Common Language Runtime (CLR) garbage collector, so if you forget to release them, the application will have a memory leak.

Because you are dealing directly with memory buffers, the normal safety checks performed by C# are not available, such as making sure you are not exceeding the bounds of an array. It is recommended that you always test your code carefully and always save your current project before debugging or executing the program.

Event Handlers

SocketTools uses events to notify the application when some change in status occurs, such as when data is available to be read. An event handler is simply a callback function which has a specific set of arguments, and the address of that function is passed to the **RegisterEvent** function in the library. However, C# doesn't permit you to simply pass the address of a function in the same way that you can in C++. Instead, you need to use what are called delegates. In .NET, a delegate is a reference type that is used to encapsulate a method that has a specific set of arguments, known as its signature. Although delegates can seem confusing at first, it is easiest to think of them as function pointers. They're basically used in the same way that function pointers are used in C++, except that they're type-safe.

The first step to creating an event handler is to create a method in your class which matches the signature of the callback function defined by the SocketTools event notification function. When the event handler is called, SocketTools will pass the handle to the client session, an event identifier to specify which event occurred, an error code value if an error occurred, and the user-defined value that was specified by the caller when the event was registered. In C++, the callback function would be declared as:

```
VOID EventHandler(HCLIENT hClient,
                 UINT nEventId,
                 DWORD dwError,
                 DWORD_PTR dwParam)
```

In C#, the equivalent method would be defined inside the class as:

```
private void EventHandler(IntPtr hClient,
                          uint nEventId,
                          uint dwError,
                          IntPtr dwParam)
```

Let's create an event handler that updates a progress bar as a file is being downloaded from an HTTP server. To do this, we'll create a method called `httpEventHandler`:

```
private void httpEventHandler(IntPtr hClient, uint nEventId, uint dwError, IntPtr
dwParam)
{
    switch (nEventId)
    {
        case HTTP_EVENT_PROGRESS:
        {
            HTTPTRANSFERSTATUS httpStatus = new HTTPTRANSFERSTATUS();
            HttpGetTransferStatus(hClient, ref httpStatus);

            progressBar1.Value = (int)((double)(100.0 *
                (double)httpStatus.dwBytesCopied /
                (double)httpStatus.dwBytesTotal));
        }
        break;
    }
}
```

This event handler checks to see if the event ID indicates that it is a progress event, and if it is, creates a `HTTPTRANSFERSTATUS` structure and calls **HttpGetTransferStatus** to determine the number of bytes which have been copied so far. This is used to calculate a percentage and a progress bar control is updated with that value.

Now that the event handler has been written, the next step is to create the event delegate for the method. For each of the SocketTools networking libraries that support event notification, there is a delegate defined, such as **HttpEventDelegate**. The delegate is created using code like this:

```
HttpEventDelegate httpEventProc = new HttpEventDelegate(httpEventHandler);
```

The `httpEventProc` variable is now like a function pointer which can be passed to **HttpRegisterEvent** in order to enable notification for that event:

```
int nResult = HttpRegisterEvent(
    hClient,
    HTTP_EVENT_PROGRESS,
    httpEventProc,
    0);
```

The first argument to **HttpRegisterEvent** is the handle to the client session. The second argument is the event ID for which you want to enable notification, the third argument is the event delegate, and the fourth

argument is a user-defined value. That same value is passed to the event handler as the dwParam argument. Your event handler is now registered, and SocketTools will call your event handler during the process of downloading or uploading a file to notify you of the progress of the transfer.

Microsoft Visual Basic .NET

The SocketTools Library Edition provides a Visual Basic module in the Include folder named `cstools11.vb` which can be included with your projects. This defines the constants and functions in the SocketTools libraries.

String Arguments

An important consideration when using the SocketTools libraries in Visual Basic is how string arguments are being used by the function. In most cases, the string is provided as input to the function, such as the hostname or address of a server to establish a connection with. However, in some cases the string is passed to the function as an output buffer into which the function copies data. For example, the **InetGetLocalName** function stores the local host name into a string parameter. A Visual Basic programmer may write code that looks like this:

```
Dim strLocalName As String
Dim nLength As Integer

nLength = InetGetLocalName(strLocalName, 256)
```

Although this code looks correct, it will invariably result in a general protection fault or some other unpredictable error. The problem is that although the *strLocalName* variable has been defined, no memory has been allocated for it. To do this, you need to declare the string as:

```
Dim strLocalName As String = New String(Chr(0), 256)
Dim nLength As Long

nLength = InetGetLocalName(strLocalName, 256)
```

This will create a string that is filled with null characters. However, when the function returns the string, it will be padded with those null characters and they should be removed. The complete example would be written in Visual Basic as:

```
Dim strLocalName As String = New String(Chr(0), 256)
Dim nLength As Long

nLength = InetGetLocalName(strLocalName, 256)
strLocalName = Strings.Left(strLocalName, nLength)
```

Because the function returns the length of the string, the Left method can be used to truncate the string using that length. However, if the function does not return the string length, you'll need to use the TrimEnd method to trim the string at the terminating null character, such as:

```
' Trim string up to the terminating null character
strLocalName = strLocalName.TrimEnd(vbNullChar.ToCharArray())
```

The first method is more efficient, but requires that the function return the number of characters it copied into the string. The second method is slightly less efficient, but will work even if the function does not return the string length.

Byte Array Arguments

A number of SocketTools functions use byte arrays, either as an input argument to the function, or as an output argument which will contain data when the function returns. An example of this is the **HttpGetData** function, which will access a resource on the server and return the contents of that resource in a byte array passed to the function. For example, the following code in C++ would return the first 1024 bytes of the index page on a webserver:

```
BYTE byteBuffer[1024];
DWORD dwLength;
INT nResult;
```

```

dwLength = sizeof(byteBuffer);
nResult = HttpGetData(hClient,
    "/index.html",
    byteBuffer,
    &dwLength,
    0);

```

If the function is successful, the `byteBuffer` array will contain the first 1024 bytes of the index page. In Visual Basic.NET, the equivalent code would look like this:

```

Dim byteBuffer(1024) As Byte
Dim dwLength As Long
Dim nResult As Long

dwLength = UBound(byteBuffer)
nResult = HttpGetData(hClient, _
    "/index.html", _
    byteBuffer(0), _
    dwLength, _
    0)

```

In C++, byte arrays can be used interchangeably with ANSI strings. However, in Visual Basic.NET you will need to use the **System.Text.Encoding** class to convert a byte array into a string. For example:

```

Dim strBuffer As String
Dim Encoding As System.Text.Encoding = _
    System.Text.Encoding.GetEncoding(1252)

strBuffer = Encoding.GetString(byteBuffer).Substring(0, dwLength)

```

This would convert the contents of the byte array into a String. Note that you should only do this if the data returned by the function is actually text. In this example, it is acceptable to do because the byte array contains the HTML text for the index page. Note that the encoding is also explicitly set to code page 1252 (ISO Latin 1), which ensures that any characters with the high bit set are converted correctly.

Global Memory Handles

In addition to using byte arrays, some `SocketTools` functions can use global memory handles (HGLOBALS) to exchange large amounts of data. Using the Windows API, global memory handles are allocated by the **GlobalAlloc** function, dereferenced by the **GlobalLock** function and released by the **GlobalFree** function. These handles can be used in Visual Basic.NET with the helper functions defined in the `SocketTools` module.

An application may choose to use a global memory handle instead of a pre-allocated buffer if the amount of data is very large, or the total amount of data that will be returned is unknown at the time the function is being called. Consider the call to the **HttpGetData** function used in the previous example. A pre-allocated buffer of 1024 bytes was passed to the function, and it copied up to that amount of data into the buffer. However, what if you wanted the complete page and did not know how large it was? You could attempt to determine the size of the page that was being requested using the **HttpGetFileSize** function, and then use that value to allocate a buffer. However, this incurs additional overhead and it is not always possible to get the size of a resource on a web server. Another alternative would be to simply allocate a very large buffer, but this could result in the application allocating large amounts of memory that it doesn't use and you would still run the risk that it wouldn't be large enough.

The solution for this problem is to use a global memory handle rather than a pre-allocated buffer. Instead of copying the data into a buffer, the function allocates a global memory handle and stores the contents in the memory referenced by that handle. When the function returns, it passes the handle back to the caller. The caller then dereferences the handle to access the memory, and releases the handle when it is no longer needed. Here is an example of how it would be used in C/C++:

```

HGLOBAL hgblBuffer = NULL;
DWORD dwLength = 0;
INT nResult;

nResult = HttpGetData(hClient,
                      "/index.html",
                      &hgblBuffer,
                      &dwLength,
                      0);

if (nResult != HTTP_ERROR)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}

```

Note that the global memory handle is initialized to NULL and the length argument is initialized to zero. This is important to do because this is how the function knows that it should be returning a global memory handle instead of copying data into a buffer. If you forget to initialize those arguments, the function will fail and may cause the application to terminate with a general protection fault.

The equivalent code in Visual Basic.NET would look like this:

```

Dim hgblBuffer As Integer = 0
Dim dwLength As Integer = 0
Dim nResult As Long

nResult = HttpGetData(hClient,
                      "/index.html",
                      hgblBuffer,
                      dwLength,
                      0);

If nResult <> HTTP_ERROR Then
    Dim lpBuffer As IntPtr
    Dim byteBuffer() As Byte
    ReDim byteBuffer(dwLength - 1)

    ' Lock the global memory handle and copy the
    ' contents of the buffer into the byte array
    lpBuffer = GlobalLock(hgblBuffer)
    CopyMemory(byteBuffer(0), lpBuffer, dwLength)

    ' Unlock and release the global memory handle
    GlobalUnlock(hgblBuffer)
    GlobalFree(hgblBuffer)

    ' Do something with the data
End If

```

If you wanted to convert the contents of the global memory buffer into a string, the Marshal class has a helper function which enables you to do this easily. To use it, you should import **System.Runtime.InteropServices** and then use the **PtrToStringAnsi** method. For example:

```

If nResult <> HTTP_ERROR Then

```

```

        ByVal dwParam As IntPtr)
    Select Case nEventId
    Case HTTP_EVENT_PROGRESS
        Dim httpStatus As HTTPTRANSFERSTATUS
        HttpGetTransferStatus(hClient, httpStatus)
        ProgressBar1.Value = CInt(100.0# * _
            CDb1(httpStatus.dwBytesCopied) / _
            CDb1(httpStatus.dwBytesTotal))
    End Select
End Sub

```

This event handler checks to see if the event ID indicates that it is a progress event, and if it is, calls **HttpGetTransferStatus** to determine the number of bytes that have been copied so far. This is used to calculate a percentage and a progress bar control is updated with that value.

Now that the event handler has been written, the next step is to create the event delegate for the method. For each of the SocketTools networking libraries that support event notification, there is a delegate type defined. The delegate is created using code like this:

```

Dim httpEventProc As HttpEventDelegate = New HttpEventDelegate(AddressOf
HttpEventHandler)

```

The httpEventProc variable is now like a function pointer which can be passed to HttpRegisterEvent in order to enable notification for that event:

```

nResult = HttpRegisterEvent( _
    hClient, _
    HTTP_EVENT_PROGRESS, _
    httpEventProc, _
    0)

```

The first argument to **HttpRegisterEvent** is the handle to the client session. The second argument is the event ID for which you want to enable notification, the third argument is the event delegate, and the fourth argument is a user-defined value. That same value is passed to the event handler as the dwParam argument.

Your event handler is now registered, and SocketTools will call your event handler during the process of downloading or uploading a file to notify you of the progress of the transfer.

Microsoft Visual Basic 6.0

The SocketTools Library Edition provides a module for Visual Basic 6.0 in the Include folder named cstools11.bas which can be included with your projects. This defines the constants and functions in the SocketTools libraries. It is recommended that you install at least Visual Studio 6.0 Service Pack 5 (SP5) for Visual Basic 6.0.

Note that because this module is very large, Visual Basic may report an error when attempting to compile a program that uses it. This is a limitation of Visual Basic and doesn't indicate a problem with the module itself. To resolve the problem, you can copy the declarations that you need into your own private module and use those instead.

An alternative to using the function declarations in a module is to create a reference to the library in your project. Although the SocketTools libraries are not ActiveX DLLs, they do contain a type library resource which defines the constants and functions for that specific library. To create a reference to the library, first open your current project or create a new project. Then select the Project | References menu option. This will display a dialog box that lists the currently selected and available references. Click on the browse button and choose the appropriate library from the Windows system directory. The following libraries can be referenced:

Library Name	Library Description
csdnsv11.dll	Domain Name Service
csftpv11.dll	File Transfer Protocol
cshtpv11.dll	Hypertext Transfer Protocol
csicmv11.dll	Internet Control Message Protocol
csmapv11.dll	Internet Message Access Protocol
csmsgv11.dll	Mail Message
csmtpv11.dll	Simple Mail Transfer Protocol
csncdv11.dll	File Encoding Library
csnvtv11.dll	Terminal Emulation
csnwsv11.dll	Network News Transfer Protocol
cspopv11.dll	Post Office Protocol
csrshv11.dll	Remote Command Protocol
csrssv11.dll	News Feed Library
cstimv11.dll	Time Protocol
cstntv11.dll	Telnet Protocol
cstxtv11.dll	Text Message Library
cswhov11.dll	Whois Protocol
cswskv11.dll	SocketWrench (Windows Sockets)

Note that if you have the SocketTools ActiveX Edition installed, there may be references to the SocketTools controls included in the list. You do not want to select these since they refer to the ActiveX controls, not the libraries. Once the library has been referenced, you will be able to use the functions and constants detailed in the technical reference.

String Arguments

An important consideration when using the SocketTools libraries in Visual Basic is how string arguments are being used by the function. In most cases, the string is provided as input to the function, such as the hostname or address of a server to establish a connection with. However, in some cases the string is passed to the function as an output buffer into which the function copies data. For example, the **InetGetLocalName** function stores the local host name into a string parameter. A Visual Basic programmer may write code that looks like this:

```
Dim strLocalName As String
Dim nLength As Long

nLength = InetGetLocalName(strLocalName, 256)
```

Although this code looks correct, it will invariably result in a general protection fault or some other unpredictable error. The problem is that although the *strLocalName* variable has been defined, no memory has been allocated for it. There are two ways this can be done in Visual Basic. One is to declare the string as fixed-length, such as:

```
Dim strLocalName As String * 256
Dim nLength As Long

nLength = InetGetLocalName(strLocalName, 256)
```

The other is to dynamically allocate memory for the string using the **String** function, such as:

```
Dim strLocalName As String
Dim nLength As Long

strLocalName = String(256, 0)
nLength = InetGetLocalName(strLocalName, 256)
```

One final consideration is that string data returned by the function will be null-terminated. Because Visual Basic strings are managed differently, we need to remove the trailing null characters. The complete example would be written in Visual Basic as:

```
Dim strLocalName As String
Dim nLength As Long

strLocalName = String(256, 0)
nLength = InetGetLocalName(strLocalName, 256)
strLocalName = Left(strLocalName, nLength)
```

Because the function returns the length of the string, the Left function can be used to truncate the string using that length. However, if the function does not return the string length, you'll need to search for the terminating null character and trim the string from that position, such as:

```
' Trim string up to the terminating null character
strLocalName = Left(strLocalName, InStr(strLocalName, Chr(0))-1)
```

The first method is more efficient, but requires that the function return the number of characters it copied into the string. The second method is slightly less efficient, but will work even if the function does not return the string length.

Byte Array Arguments

A number of SocketTools functions use byte arrays, either as an input argument to the function, or as an output argument which will contain data when the function returns. An example of this is the **HttpGetData** function, which will access a resource on the server and return the contents of that resource in a byte array passed to the function. For example, the following code in C++ would return the first 1024 bytes of the index page on a webserver:

```

BYTE byteBuffer[1024];
DWORD dwLength;
INT nResult;

dwLength = sizeof(byteBuffer);
nResult = HttpGetData(hClient,
                      "/index.html",
                      byteBuffer,
                      &dwLength,
                      0);

```

If the function is successful, the `byteBuffer` array will contain the first 1024 bytes of the index page. In Visual Basic 6.0, the equivalent code would look like this:

```

Dim byteBuffer(1024) As Byte
Dim dwLength As Long
Dim nResult As Long

dwLength = UBound(byteBuffer)
nResult = HttpGetData(hClient, _
                      "/index.html", _
                      byteBuffer(0), _
                      dwLength, _
                      0)

```

In C++, byte arrays can be used interchangeably with ANSI strings. However, in Visual Basic you will need to use the **StrConv** function to convert a byte array into a string. For example:

```

Dim strBuffer As String
strBuffer = Left(StrConv(byteBuffer, vbUnicode), dwLength)

```

This would convert the contents of the byte array into a String. Note that you should only do this if the data returned by the function is actually text. In this example, it is acceptable to do because the byte array contains the HTML text for the index page.

Global Memory Handles

In addition to using byte arrays, some `SocketTools` functions can use global memory handles (HGLOBALS) to exchange large amounts of data. Using the Windows API, global memory handles are allocated by the **GlobalAlloc** function, dereferenced by the **GlobalLock** function and released by the **GlobalFree** function. These handles can be used in Visual Basic with the helper functions defined in the `SocketTools` module.

An application may choose to use a global memory handle instead of a pre-allocated buffer if the amount of data is very large, or the total amount of data that will be returned is unknown at the time the function is being called. Consider the call to the **HttpGetData** function used in the previous example. A pre-allocated buffer of 1024 bytes was passed to the function, and it copied up to that amount of data into the buffer. However, what if you wanted the complete page and did not know how large it was? You could attempt to determine the size of the page that was being requested using the **HttpGetFileSize** function, and then use that value to allocate a buffer. However, this incurs additional overhead and it is not always possible to get the size of a resource on a web server. Another alternative would be to simply allocate a very large buffer, but this could result in the application allocating large amounts of memory that it doesn't use and you would still run the risk that it wouldn't be large enough.

The solution for this problem is to use a global memory handle rather than a pre-allocated buffer. Instead of copying the data into a buffer, the function allocates a global memory handle and stores the contents in the memory referenced by that handle. When the function returns, it passes the handle back to the caller. The caller then dereferences the handle to access the memory, and releases the handle when it is no longer needed. Here is an example of how it would be used in C/C++:

```

HGLOBAL hgblBuffer = NULL;
DWORD dwLength = 0;
INT nResult;

nResult = HttpGetData(hClient,
                      "/index.html",
                      &hgblBuffer,
                      &dwLength,
                      0);

if (nResult != HTTP_ERROR)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}

```

Note that the global memory handle is initialized to NULL and the length argument is initialized to zero. This is important to do because this is how the function knows that it should be returning a global memory handle instead of copying data into a buffer. If you forget to initialize those arguments, the function will fail and may cause the application to terminate with a general protection fault.

To work with the global memory handles used by SocketTools, you will need to define a few standard functions that are part of the Windows operating system:

```

Declare Function GlobalLock Lib "kernel32.dll" ( _
    ByVal hMem As Long _
) As Long

Declare Function GlobalUnlock Lib "kernel32.dll" ( _
    ByVal hMem As Long _
) As Long

Declare Function GlobalFree Lib "kernel32.dll" ( _
    ByVal hMem As Long _
) As Long

Declare Sub CopyMemory Lib "kernel32.dll" _
    Alias "RtlMoveMemory" ( _
    ByRef lpDestination As Byte, _
    ByVal lpSource As Long, _
    ByVal dwLength As Long)

```

The **GlobalLock** function is used to dereference a global memory handle, returning the address in memory where the data is stored. The **GlobalUnlock** function is used to unlock a memory handle that was previously locked with a call to **GlobalLock**. The **GlobalFree** function releases the memory back to the operating system. The **CopyMemory** function is used to copy the data into a byte array that your program has allocated.

Because the function declaration for the **HttpGetData** function expects you to pass a byte array, you will need to redefine the function in a private module. Note that this declaration will override how the function is declared if you have referenced the library. The standard function declaration for **HttpGetData** looks like this:

```

Declare Function HttpGetData Lib "cshttpv11.dll" _
    Alias "HttpGetDataA" ( _
    ByVal hClient As Long, _
    ByVal lpSzResource As String, _

```

```

ByRef lpBuffer As Byte, _
ByRef lpdwLength As Long, _
ByVal dwOptions As Long _
) As Long

```

The new declaration should be modified so that the third argument is changed to a Long passed by reference:

```

Declare Function HttpGetData Lib "cshttpv11.dll" _
Alias "HttpGetDataA" ( _
ByVal hClient As Long, _
ByVal lpszResource As String, _
ByRef hgblBuffer As Long, _
ByRef lpdwLength As Long, _
ByVal dwOptions As Long _
) As Long

```

That long integer will contain the global memory handle allocated by the function when it returns. With these changes, the equivalent code in Visual Basic 6.0 would look like this:

```

Dim hgblBuffer As Long
Dim dwLength As Long
Dim nResult As Long

hgblBuffer = 0
dwLength = 0

nResult = HttpGetData(hClient,
                      "/index.html",
                      hgblBuffer,
                      dwLength,
                      0);

If nResult <> HTTP_ERROR Then
    Dim lpBuffer As Long
    Dim byteBuffer() As Byte
    ReDim byteBuffer(dwLength - 1)

    lpBuffer = GlobalLock(hgblBuffer)
    CopyMemory byteBuffer(0), lpBuffer, dwLength

    Dim strBuffer As String
    strBuffer = StrConv(byteBuffer, vbUnicode)

    GlobalUnlock hgblBuffer
    GlobalFree hgblBuffer
End If

```

It is important to remember to unlock and release the global memory handle when you are no longer using it. If you forget to release them, the application will have a memory leak. Because you are dealing directly with memory buffers, the normal safety checks performed by Visual Basic are not available, such as making sure you are not exceeding the bounds of an array. Simple mistakes such as passing an incorrect argument or the wrong buffer size can result in Visual Basic becoming unstable or terminating with a general protection fault. It is recommended that you always test your code carefully and always save your current project before debugging or executing the program.

Event Handlers

SocketTools uses events to notify the application when some change in status occurs, such as when data is available to be read or progress notifications during a file transfer. An event handler is simply a callback function which has a specific set of arguments, and the address of that function is passed to the

HttpRegisterEvent function in the library. In Visual Basic 6.0, you can use the **AddressOf** operator to obtain the address of a public callback function to pass to the function.

The first step to creating an event handler is to create a function which matches the signature of the callback function defined by the SocketTools event notification function. Your event handler must be created in a module, not a class or form, and you must declare it as public. When the event handler is called, SocketTools will pass the handle to the client session, an event identifier to specify which event occurred, an error code value if an error occurred, and the user-defined value that was specified by the caller when the event was registered. In C++, the callback function would be declared as:

```
VOID EventHandler(HCLIENT hClient,
                 UINT nEventId,
                 DWORD dwError,
                 DWORD_PTR dwParam)
```

In Visual Basic, the equivalent method would be defined as:

```
Public Sub HttpEventHandler(ByVal hClient As Long, _
                          ByVal nEventId As Long, _
                          ByVal dwError As Long, _
                          ByVal dwParam As Long)
```

Let's create an event handler that updates a progress bar as a file is being downloaded from an HTTP server. To do this, we'll create a function called **HttpEventHandler**:

```
Public Sub HttpEventHandler(ByVal hClient As Long, _
                          ByVal nEventId As Long, _
                          ByVal dwError As Long, _
                          ByVal dwParam As Long)

    Select Case nEventId
    Case HTTP_EVENT_PROGRESS
        Dim httpStatus As HTTPTRANSFERSTATUS
        HttpGetTransferStatus hClient, httpStatus
        Form1.ProgressBar1.Value = CInt(100# * _
            Cdbl(httpStatus.dwBytesCopied) / _
            Cdbl(httpStatus.dwBytesTotal))
    End Select
End Sub
```

This event handler checks to see if the event ID indicates that it is a progress event, and if it is, calls **HttpGetTransferStatus** to determine the number of bytes which have been copied so far. This is used to calculate a percentage and a progress bar control is updated with that value.

Now that the event handler has been written, the next step is to register the event handler with the library:

```
nResult = HttpRegisterEvent( _
    hClient, _
    HTTP_EVENT_PROGRESS, _
    AddressOf HttpEventHandler, _
    0)
```

The first argument to **HttpRegisterEvent** is the handle to the client session. The second argument is the event ID that you want to enable notification for, the third argument is the address of the event handler, and the fourth argument is a user-defined value. That same value is passed to the event handler as the dwParam argument.

Your event handler is now registered, and SocketTools will call your event handler during the process of downloading or uploading a file to notify you of the progress of the transfer.

Borland Delphi

The SocketTools Library Edition provides a Delphi unit in the Include folder named `cstools11.pas` which can be included with your projects. This defines the constants and functions in the SocketTools libraries.

String Arguments

An important consideration when using the SocketTools libraries in Delphi is how string arguments are being used by the function. In most cases, the string is provided as input to the function, such as the hostname or address of a server to establish a connection with. However, in some cases the string is passed to the function as an output buffer into which the function copies data. An example of this would be the **HttpGetErrorString** function, which is used to obtain a description of a specific error. In C/C++ you would allocate a character array and pass it to the function, such as:

```
VOID ShowError()
{
    TCHAR szError[256];
    DWORD dwError;

    dwError = HttpGetLastError();
    if (dwError > 0)
    {
        HttpGetErrorString(dwError, szError, 256);
        MessageBox(NULL, szError, "Error", MB_OK);
    }
}
```

Delphi has a type called **PAnsiChar** which is a pointer to a null terminated array of characters. It was created primarily as a compatibility type to work with the Windows API and C/C++ dynamic link libraries, and this is the type that the SocketTools functions use to represent strings. The equivalent code in Delphi would be:

```
procedure ShowError;
var
    dwError: LongWord;
    szError: Array [0..255] Of AnsiChar;
begin
    dwError := HttpGetLastError();
    if dwError > 0 then;
    begin
        HttpGetErrorString(dwError, szError, 256);
        ShowMessage(szError);
    end;
end;
```

Early versions of Delphi had helper functions such as **StrNew** to help convert and allocate null terminated strings. However, those functions have been deprecated and in most cases current versions of Delphi will automatically convert between character arrays and its native **String** type. There are also a number of functions available which are designed specifically to work with null terminated strings. Refer to your language reference for more information about how Delphi uses null terminated strings.

Byte Array Arguments

A number of SocketTools functions use byte arrays, either as an input argument to the function, or as an output argument which will contain data when the function returns. An example of this is the **HttpGetData** function, which will access a resource on the server and return the contents of that resource in a byte array passed to the function. For example, the following code in C++ would return the first 1024 bytes of the index page on a web server:

```
BYTE byteBuffer[1024];
```

```

DWORD dwLength;
INT nResult;

dwLength = sizeof(byteBuffer);
nResult = HttpGetData(hClient,
                      "/index.html",
                      byteBuffer,
                      &dwLength,
                      0);

```

If the function is successful, the `byteBuffer` array will contain the first 1024 bytes of the index page. In Delphi, the equivalent code would look like this:

```

var
  nResult: Integer;
  byteBuffer: Array [0..1023] Of Byte;
  dwLength: LongWord;
begin
  dwLength := 1024;
  nResult := HttpGetData(hClient,
                        PAnsiChar('/index.html'),
                        @byteBuffer,
                        dwLength,
                        0);

end;

```

In this example, you will notice that the string was explicitly cast to a null terminated string using `PAnsiChar`. This is necessary because the **HttpGetData** function is overloaded and Delphi will complain that the function cannot be found if the cast is omitted.

If you wanted to convert the data in the byte array to a `String` type, you might think that you could do something like this:

```

strBuffer := PAnsiChar(@byteBuffer);

```

This may appear to work, but it would depend on there being a null character to terminate the byte array and it could result in garbage characters appearing at the end of your string or cause the program to attempt to read memory that it has not allocated. To convert the byte array into a string, use the following:

```

SetLength(strBuffer, dwLength);
Move(byteBuffer, strBuffer[1], dwLength);

```

Note that you should only do this if the data returned by the function is actually text. In this example, it is acceptable to do because the byte array contains the HTML text for the index page.

Global Memory Handles

In addition to using byte arrays, some `SocketTools` functions can use global memory handles (HGLOBALS) to exchange large amounts of data. Using the Windows API, global memory handles are allocated by the **GlobalAlloc** function, dereferenced by the **GlobalLock** function and released by the **GlobalFree** function. These handles can be used in Delphi with the helper functions defined in the `SocketTools` unit.

An application may choose to use a global memory handle instead of a pre-allocated buffer if the amount of data is very large, or the total amount of data that will be returned is unknown at the time the function is being called. Consider the call to the **HttpGetData** function used in the previous example. A pre-allocated buffer of 1024 bytes was passed to the function, and it copied up to that amount of data into the buffer. However, what if you wanted the complete page and did not know how large it was? You could attempt to determine the size of the page that was being requested using the **HttpGetFileSize** function, and then use that value to allocate a buffer. However, this incurs additional overhead and it is not always possible to get the size of a resource on a web server. Another alternative would be to simply allocate a very large buffer, but this could result in the

application allocating large amounts of memory that it doesn't use and you would still run the risk that it wouldn't be large enough.

The solution for this problem is to use a global memory handle rather than a pre-allocated buffer. Instead of copying the data into a buffer, the function allocates a global memory handle and stores the contents in the memory referenced by that handle. When the function returns, it passes the handle back to the caller. The caller then dereferences the handle to access the memory, and releases the handle when it is no longer needed. Here is an example of how it would be used in C/C++:

```
HGLOBAL hgblBuffer = NULL;
DWORD dwLength = 0;
INT nResult;

nResult = HttpGetData(hClient,
                      "/index.html",
                      &hgblBuffer,
                      &dwLength,
                      0);

if (nResult != HTTP_ERROR)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}
```

Note that the global memory handle is initialized to NULL and the length argument is initialized to zero. This is important to do because this is how the function knows that it should be returning a global memory handle instead of copying data into a buffer. If you forget to initialize those arguments, the function will fail and may cause the application to terminate with a general protection fault.

The equivalent code in Delphi would look like this:

```
var
    nResult: Integer;
    hgblBuffer: LongWord;
    dwLength: LongWord;
    pszBuffer: PAnsiChar;
begin
    hgblBuffer := 0;
    dwLength := 0;

    nResult := HttpGetData(hClient,
                          PChar('/index.html'),
                          hgblBuffer,
                          dwLength,
                          0);

    if nResult <> HTTP_ERROR then
    begin
        pszBuffer := PAnsiChar(GlobalLock(hgblBuffer));

        { Do something with the data and then unlock and
          release the handle when it is no longer needed }
```

```

        GlobalUnlock(hgblBuffer);
        GlobalFree(hgblBuffer);
    end;
end;

```

It is important to remember to unlock and release the global memory handle when you are no longer using it. If you forget to release them, the application will have a memory leak.

Event Handlers

SocketTools uses events to notify the application when some change in status occurs, such as when data is available to be read or progress notifications during a file transfer. An event handler is simply a callback function which has a specific set of arguments, and the address of that function is passed to the ***RegisterEvent*** function in the library.

The first step to creating an event handler is to create a function which matches the signature of the callback function defined by the SocketTools event notification function. When the event handler is called, SocketTools will pass the handle to the client session, an event identifier to specify which event occurred, an error code value if an error occurred, and the user-defined value that was specified by the caller when the event was registered. In C++, the callback function would be declared as:

```

VOID EventHandler(HCLIENT hClient,
                 UINT nEventId,
                 DWORD dwError,
                 DWORD_PTR dwParam)

```

In Delphi, the equivalent function would be defined as:

```

procedure EventHandler(
    hClient: Integer;
    nEventId: Integer;
    dwError: LongWord;
    dwParam: LongWord); stdcall;

```

Note that the stdcall has been specified for the function. This is important, because the SocketTools libraries require the stdcall calling convention, as do any Windows API functions which use callback functions. Failure to specify the correct calling convention can prevent the callback function from being invoked or can cause the application to terminate abnormally.

Let's create an event handler that updates a progress bar as a file is being downloaded from an HTTP server. To do this, we'll create a procedure called **HttpEventHandler**:

```

procedure HttpEventHandler(
    hClient: Integer;
    nEventId: Integer;
    dwError: LongWord;
    dwParam: LongWord); stdcall;
var
    httpStatus: HTTPTRANSFERSTATUS;
    nPercent: Integer;
begin
    if nEventId = HTTP_EVENT_PROGRESS then
    begin
        HttpGetTransferStatus(hClient, httpStatus);
        nPercent := Trunc(100.0 * httpStatus.dwBytesCopied /
                           httpStatus.dwBytesTotal);
        Form1.ProgressBar1.Position := nPercent;
    end;
end;

```

This event handler checks to see if the event ID indicates that it is a progress event, and if it is, calls

HttpGetTransferStatus to determine the number of bytes that have been copied so far. This is used to calculate a percentage and a progress bar control is updated with that value.

Now that the event handler has been written, the next step is to register the event with the library so that it is called during the transfer. To do this, the **HttpRegisterEvent** function is called to enable notification for the progress event:

```
nResult := HttpRegisterEvent(  
    hClient,  
    HTTP_EVENT_PROGRESS,  
    @HttpEventHandler,  
    0);
```

The first argument to **HttpRegisterEvent** is the handle to the client session. The second argument is the event ID for which you want to enable notification, the third argument is the address of the callback function, and the fourth argument is a user-defined value. That same value is passed to the event handler as the dwParam argument.

Your event handler is now registered, and SocketTools will call your event handler during the process of downloading or uploading a file to notify you of the progress of the transfer.

The SocketTools Library Edition provides a complete set of function declarations and constants in the Include folder named `cstools11.inc` which can be included with your projects. The function declarations and examples included with SocketTools were developed using PowerBASIC 10.0 and PBForms 2.0. The function declarations are also compatible with the PowerBASIC 6.0 console compiler.

String Arguments

An important consideration when using the SocketTools libraries in PowerBASIC is how string arguments are used by the function. In most cases, the string is provided as input to the function, such as the hostname or address of a server to establish a connection with. However, in some cases the string is passed to the function as an output buffer into which the function copies data. An example of this would be the **HttpGetErrorString** function, which is used to obtain a description of a specific error. In C/C++ you would allocate a character array and pass it to the function, such as:

```
VOID ShowError()  
{  
    TCHAR szError[256];  
    DWORD dwError;  
  
    dwError = HttpGetLastError();  
    if (dwError > 0)  
    {  
        HttpGetErrorString(dwError, szError, 256);  
        MessageBox(NULL, szError, "Error", MB_OK);  
    }  
}
```

PowerBASIC has a string type called `STRINGZ` which is null terminated, fixed-length string and is compatible with how strings are passed to the functions in the SocketTools API. Note that earlier versions of PowerBASIC called them `ASCIIZ` strings. The equivalent code would be:

```
SUB ShowError()  
    LOCAL szError AS STRINGZ * 256  
    LOCAL dwError AS DWORD  
  
    dwError = HttpGetLastError()  
    IF dwError <> 0 THEN  
        HttpGetErrorString(dwError, szError, SIZEOF(szError))  
        MSGBOX szError, %MB_OK OR %MB_ICONEXCLAMATION, "Error"  
    END IF  
END SUB
```

It is important to note that you should generally not use `STRING` types, since those represent variable length strings.

Byte Array Arguments

A number of SocketTools functions use byte arrays, either as an input argument to the function, or as an output argument which will contain data when the function returns. An example of this is the **HttpGetData** function, which will access a resource on the server and return the contents of that resource in a byte array passed to the function. For example, the following code in C++ would return the first 1024 bytes of the index page on a webserver:

```
BYTE byteBuffer[1024];  
DWORD dwLength;  
INT nResult;
```

```

dwLength = sizeof(byteBuffer);
nResult = HttpGetData(hClient,
    "/index.html",
    byteBuffer,
    &dwLength,
    0);

```

If the function is successful, the byteBuffer array will contain the first 1024 bytes of the index page. In PowerBASIC, the equivalent code would look like this:

```

DIM byteBuffer(1024) AS LOCAL BYTE
LOCAL dwLength AS DWORD
LOCAL nResult AS LONG

dwLength = SIZEOF(byteBuffer)
nResult = HttpGetData(hClient, _
    "/index.html", _
    BYREF byteBuffer(0), _
    dwLength, _
    0)

```

In this example, you will notice that the byteBuffer array is passed by reference, specifying the first element. The function will fill the byte array up to the number of bytes specified by the dwLength argument; when the function returns, dwLength will be updated with the actual number of bytes copied into the buffer.

If you wanted to convert the data in the byte array to a string type, you can terminate the data with a null character. However, this means that you should reserve a byte in the array. For example:

```

DIM byteBuffer(1024) AS LOCAL BYTE
LOCAL lpszBuffer AS STRINGZ PTR
LOCAL dwLength AS DWORD
LOCAL nResult AS LONG

dwLength = SIZEOF(byteBuffer) - 1 ' Reserve space for the null
nResult = HttpGetData(hClient, _
    "/index.html", _
    BYREF byteBuffer(0), _
    dwLength, _
    0)

IF nResult <> %HTTP_ERROR THEN
    lpszBuffer = VARPTR(byteBuffer(0))
    CONTROL SET TEXT hDlg, hCt1, @lpszBuffer
END IF

```

Note that you should only do this if the data returned by the function is actually text. In this example, it is acceptable to do because the byte array contains the HTML text for the index page.

Global Memory Handles

In addition to using byte arrays, some SocketTools functions can use global memory handles (HGLOBALSs) to exchange large amounts of data. Using the Windows API, global memory handles are allocated by the **GlobalAlloc** function, dereferenced by the **GlobalLock** function and released by the **GlobalFree** function. These functions are defined in the WIN32API.INC module that is included with the language.

An application may choose to use a global memory handle instead of a pre-allocated buffer if the amount of data is very large, or the total amount of data that will be returned is unknown at the time the function is being called. Consider the call to the **HttpGetData** function used in the previous example. A pre-allocated buffer of 1024 bytes was passed to the function, and it copied up to that amount of data into the buffer. However, what if you wanted the complete page and did not know how large it was? You could attempt to determine the size

of the page that was being requested using the **HttpGetFileSize** function, and then use that value to allocate a buffer. However, this incurs additional overhead and it is not always possible to get the size of a resource on a web server. Another alternative would be to simply allocate a very large buffer, but this could result in the application allocating large amounts of memory that it doesn't use and you would still run the risk that it wouldn't be large enough.

The solution for this problem is to use a global memory handle rather than a pre-allocated buffer. Instead of copying the data into a buffer, the function allocates a global memory handle and stores the contents in the memory referenced by that handle. When the function returns, it passes the handle back to the caller. The caller then dereferences the handle to access the memory, and releases the handle when it is no longer needed. Here is an example of how it would be used in C/C++:

```
HGLOBAL hglobalBuffer = NULL;
DWORD dwLength = 0;
INT nResult;

nResult = HttpGetData(hClient,
                      "/index.html",
                      &hglobalBuffer,
                      &dwLength,
                      HTTP_TRANSFER_CONVERT);

if (nResult != HTTP_ERROR)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hglobalBuffer);

    // Do something with the data and then unlock and
    // release the handle when it is no longer needed

    GlobalUnlock(hglobalBuffer);
    GlobalFree(hglobalBuffer);
}
```

Note that the global memory handle is initialized to NULL and the length argument is initialized to zero. This is important to do because this is how the function knows that it should be returning a global memory handle instead of copying data into a buffer. If you forget to initialize those arguments, the function will fail and may cause the application to terminate with a general protection fault.

The equivalent code in PowerBASIC would look like this:

```
LOCAL hglobalBuffer AS DWORD
LOCAL dwLength AS DWORD
LOCAL pszBuffer AS STRINGZ PTR
LOCAL nResult AS LONG

hglobalBuffer = %NULL
dwLength = 0

nResult = HttpGetData(hClient, _
                      "/index.html", _
                      BYREF hglobalBuffer, _
                      dwLength, _
                      %HTTP_TRANSFER_CONVERT)

IF nResult <> %HTTP_ERROR THEN
    pszBuffer = GlobalLock(hglobalBuffer)

    ' Do something with the data and then unlock and
    ' release the handle when it is no longer needed
```

```

GlobalUnlock(hgblBuffer)
GlobalFree(hgblBuffer)
END IF

```

It is important to remember to unlock and release the global memory handle when you are no longer using it. If you forget to release them, the application will have a memory leak.

Event Handlers

SocketTools uses events to notify the application when some change in status occurs, such as when data is available to be read or progress notifications during a file transfer. An event handler is simply a callback function which has a specific set of arguments, and the address of that function is passed to the **HttpRegisterEvent** function in the library.

The first step to creating an event handler is to create a function which matches the signature of the callback function defined by the SocketTools event notification function. When the event handler is called, SocketTools will pass the handle to the client session, an event identifier to specify which event occurred, an error code value if an error occurred, and the user-defined value that was specified by the caller when the event was registered. In C++, the callback function would be declared as:

```

VOID CALLBACK EventHandler(
    HCLIENT hClient,
    UINT nEventId,
    DWORD dwError,
    DWORD_PTR dwParam)

```

In PowerBASIC, the equivalent function would be defined as:

```

SUB EventHandler STDCALL ( _
    BYVAL hClient AS LONG, _
    BYVAL nEventId AS LONG, _
    BYVAL dwError AS DWORD, _
    BYVAL dwParam AS DWORD)

```

Note that the STDCALL has been specified for the function. This is important, because the SocketTools libraries require this calling convention, as do any Windows API functions which use callback functions. Failure to specify the correct calling convention can prevent the callback function from being invoked or can cause the application to terminate abnormally.

Let's create an event handler that updates a progress bar as a file is being downloaded from an HTTP server. To do this, we'll create a subroutine called **HttpEventHandler**:

```

SUB HttpEventHandler STDCALL ( _
    BYVAL hClient AS LONG, _
    BYVAL nEventId AS LONG, _
    BYVAL dwError AS DWORD, _
    BYVAL dwParam AS DWORD)

    LOCAL httpStatus AS HTTPTRANSFERSTATUS
    LOCAL nPercent AS LONG
    LOCAL hDlg AS DWORD

    hDlg = dwParam ' Dialog with the progress bar control

    IF nEventId = %HTTP_EVENT_PROGRESS THEN
        HttpGetTransferStatus(hClient, httpStatus)
        nPercent = CLNG(100.0 * CDBL(httpStatus.dwBytesCopied) / _
            CDBL(httpStatus.dwBytesTotal))
        CONTROL SEND hDlg, %IDC_PROGRESSBAR1, %PBM_SETPOS, nPercent, 0
    END IF

```

END SUB

This event handler checks to see if the event ID indicates that it is a progress event, and if it is, calls **HttpGetTransferStatus** to determine the number of bytes that have been copied so far. This is used to calculate a percentage and a progress bar control is updated with that value.

Now that the event handler has been written, the next step is to register the event with the library so that it is called during the transfer. To do this, the **HttpRegisterEvent** function is called to enable notification for the progress event:

```
nResult = HttpRegisterEvent( _  
    hClient, _  
    %HTTP_EVENT_PROGRESS, _  
    CODEPTR(HttpEventHandler), _  
    hDlg);
```

The first argument to **HttpRegisterEvent** is the handle to the client session. The second argument is the event ID for which you want to enable notification, the third argument is the address of the callback function, and the fourth argument is a user-defined value. That same value is passed to the event handler as the dwParam argument. To update a progress bar control or any other user interface object, the dwParam argument would typically be the handle to a dialog.

Your event handler is now registered, and SocketTools will call your event handler during the process of downloading or uploading a file to notify you of the progress of the transfer.

SocketTools Library Overview

The SocketTools Library Edition includes libraries that implement fourteen standard Internet application protocols, as well as libraries which provide support for general TCP/IP networking services, encoding and compressing files, processing email messages and ANSI terminal emulation. The following libraries are included in the SocketTools Library Edition:

Application Storage

The Web Services library provides a private cloud storage API for uploading and downloading shared data files which are available to your application. This is primarily intended for use by developers to store configuration information and other data generated by the application. For example, you may want to store certain application settings, and the next time a user or organization installs your software, those settings can be downloaded and restored.

Domain Name Service

The Domain Name Service (DNS) protocol is what applications use to resolve domain names into Internet addresses, as well as provide other information about a domain, such as the name of the mail servers which are responsible for receiving email for users in that domain. The DNS library enables an application to query one or more nameservers directly, without depending on the configuration of the client system.

Encoding, Compression and Encryption

The Encoding, Compression and Encryption library provides functions for encoding and decoding binary files, typically attachments to email messages. The process of encoding converts the contents of a binary file to printable text. Decoding reverses the process, converting a previously encoded text file back into a binary file. The library supports a number of different encoding methods, including support for the base64, uucode, quoted-printable and yEnc algorithms. The library can also be used to encrypt data using AES-256 bit encryption, and compress data in a user-supplied buffer or in a file.

File Transfer Protocol

The File Transfer Protocol (FTP) library provides functions for uploading and downloading files from a server, as well as a variety of remote file management functions. In addition to file transfers, an application can create, rename and delete files and directories, list files and search for files using wildcards. The library provides both high level functions, such as the ability to transfer multiple files in a single function call, as well as access to lower level remote file I/O functions. This API supports secure file transfers using FTPS (FTP+TLS) and SFTP (FTP+SSH).

GeoIP Location

The Web Services library provides an API for obtaining geographical information about the physical location of the computer system based on its external IP address. This can enable developers to know where their application is being used, and provide convenience functionality such as automatically completing a form based on the location of the user.

Hypertext Transfer Protocol

The Hypertext Transfer Protocol (HTTP) library provides an interface for accessing documents and other types of files on a server. In some ways it is similar to the File Transfer Protocol in that it can be used to upload and download files; however, the protocol has expanded to also support remote file management, script execution and distributed authoring over the World Wide Web. The SocketTools Hypertext Transfer Protocol library implements version 0.9, 1.0 and 1.1 of the protocol, including features such as support for proxy servers, persistent connections, user-defined header fields and chunked data.

Internet Control Message Protocol

The Internet Control Message Protocol (ICMP) is commonly used to determine if a server is reachable

and how packets of data are routed to that system. Users are most familiar with this protocol as it is implemented in the ping and tracert command line utilities. The ping command is used to check if a system is reachable and the amount of time that it takes for a packet of data to make a round trip from the local system, to the server and then back again. The tracert command is used to trace the route that a packet of data takes from the local system to the server, and can be used to identify potential problems with overall throughput and latency. The library can be used to build in this type of functionality in your own applications, giving you the ability to send and receive ICMP echo datagrams in order to perform your own analysis.

Internet Message Access Protocol

The Internet Message Access Protocol (IMAP) is an application protocol which is used to access a user's email messages which are stored on a mail server. However, unlike the Post Office Protocol (POP) where messages are downloaded and processed on the local system, the messages on an IMAP server are retained on the server and processed remotely. This is ideal for users who need access to a centralized store of messages or have limited bandwidth. For example, traveling salesmen who have notebook computers or mobile users on a wireless network would be ideal candidates for using IMAP. The SocketTools IMAP library implements the current standard for this protocol, and provides functions to retrieve messages, or just certain parts of a message, create and manage mailboxes, search for specific messages based on certain criteria and so on. The API is designed as a superset of the Post Office Protocol API, so developers who are used to working with the POP3 library will find the IMAP library very easy to integrate into an existing application.

Mail Messages

The Mail Message (MIME) library provides an interface for composing and processing email messages and newsgroup articles which are structured according to the Multipurpose Internet Mail Extensions (MIME) standard. Using this library, an application can easily create complex messages which include multiple alternative content types, such as plain text and styled HTML text, file attachments and customized headers. It is not required that the developer understand the complex MIME standard; a single function call can be used to create multipart message, complete with a styled HTML text body and support for international character sets. The Mail Message library can be easily integrated with the other mail related protocol libraries, making it extremely easy to create and process MIME formatted messages.

Network News Transfer Protocol

The Network News Transfer Protocol (NNTP) is used with servers that provide news services. This is similar in functionality to bulletin boards or message boards, where topics are organized hierarchically into groups, called newsgroups. Users can browse and search for messages, called news articles, which have been posted by other users. On many servers, they can also post their own articles which can be read by others. The largest collection of public newsgroups available is called USENET, a world-wide distributed discussion system. In addition, there are a large number of smaller news servers. For example, Microsoft operates a news server which functions as a forum for technical questions and announcements. The SocketTools library provides a comprehensive interface for accessing newsgroups, retrieving articles and posting new articles. In combination with the Mail Message library to process the news articles, SocketTools can be used to integrate newsgroup access with an existing email application, or you can implement your own full-featured newsgroup client.

News Feeds

The News Feed (RSS) library enables an application to download and process a syndicated news feed in in standard format. News feeds can be accessed remotely from a web server, or locally as an XML formatted text file. The source of the feed is determined by the URI scheme that is specified. If the http or https scheme is specified, then the feed is retrieved from a web server. If the file scheme is used, the feed is considered to be local and is accessed from the disk or local network. The News Feed

library provides an API that enables you to open a feed by URL and iterate through each of the items in the feed or search for a specific feed item. The library also provides a function that can be used to parse a string that contains XML data in RSS format, where the feed may have been retrieved from other sources such as a database.

Post Office Protocol

The Post Office Protocol (POP3) provides access to a user's new email messages on a mail server. Functions are provided for listing available messages and then retrieving those messages, storing them either in files or in memory. Once a user's messages have been downloaded to the local system, they are typically removed from the server. This is the most popular email protocol used by Internet Service Providers (ISPs) and the SocketTools library provides a complete interface for managing a user's mailbox. This library is typically used in conjunction with the Mail Message library, which is used to process the messages that are retrieved from the server.

Remote Commands

The Remote Command library is used to execute a command on a server and return the output of that command to the client. The SocketTools library provides an interface to this protocol, enabling applications to remotely execute a command and process the output. This is most commonly used with UNIX based servers, although there are implementations of remote command servers for the Windows operating system. The SocketTools library supports both the rcmd and rshell remote execution protocols and provides functions which can be used to search the data stream for specific sequences of characters. This makes it extremely easy to write Windows applications which serve as light-weight client interfaces to commands being executed on a UNIX server or another Windows system. The library can also be used to establish a remote terminal session using the rlogin protocol, which is similar to how the Telnet protocol functions.

Secure Shell Protocol

The Secure Shell (SSH) protocol is used to establish a secure connection with a server which provides a virtual terminal session for a user. Its functionality is similar to how character based consoles and serial terminals work, enabling a user to login to the server, execute commands and interact with applications running on the server. The SSH library provides an API for establishing the connection and handling the standard I/O functions needed by the program. The library also provides functions that enable a program to easily scan the data stream for specific sequences of characters, making it very simple to write light-weight client interfaces to applications running on the server.

Simple Mail Transfer Protocol

The Simple Mail Transfer Protocol (SMTP) enables applications to deliver email messages to one or more recipients. The library provides an API for addressing and delivering messages, and extended features such as user authentication and delivery status notification. Unlike Microsoft's Messaging API (MAPI) or Collaboration Data Objects (CDO), there is no requirement to have certain third-party email applications installed or specific types of servers installed on the local system. The SocketTools library can be used to deliver mail through a wide variety of systems, from standard UNIX based mail servers to Windows systems running Exchange or Lotus Notes and Domino. Using the SocketTools library, messages can be delivered directly to the recipient, or they can be routed through a relay server, such as an Internet Service Provider's mail system. The Mail Message library can be integrated with this library in order to provide an extremely simple, yet flexible interface for composing and delivering mail messages.

SocketWrenchy

The SocketWrench library provides a higher-level interface to the Windows Sockets API, designed to be suitable for programming languages other than C and C++. If needed, function calls can be intermixed between the SocketWrench and Windows Sockets libraries. In addition, the SocketWrench supports secure communications using Transport Layer Security (TLS).

Telnet Protocol

The Telnet protocol is used to establish a connection with a server which provides a virtual terminal session for a user. Its functionality is similar to how character based consoles and serial terminals work, enabling a user to login to the server, execute commands and interact with applications running on the server. The Telnet library provides an API for establishing the connection, negotiating certain options (such as whether characters will be echoed back to the client) and handling the standard I/O functions needed by the program. The library also provides functions that enable a program to easily scan the data stream for specific sequences of characters, making it very simple to write light-weight client interfaces to applications running on the server. This library can be combined with the Terminal Emulation library to provide complete terminal emulation services for a standard ANSI or DEC-VT220 terminal.

Terminal Emulation

The Terminal Emulation library provides a comprehensive API for emulating an ANSI or DEC-VT220 character terminal, with full support for all standard escape and control sequences, color mapping and other advanced features. The library functions provide both a high level interface for parsing escape sequences and updating a display, as well as lower level primitives for directly managing the virtual display, such as controlling the individual display cells, moving the cursor position and specifying display attributes. This library can be used in conjunction with the Remote Command or Telnet Protocol library to provide terminal emulation services for an application, or it can be used independently. For example, this library could also be used to provide emulation services for a program that provides serial modem connections to a server.

Text Messaging

The Text Message library enables applications to send text messages to mobile devices. It provides an interface that can be used to obtain information about the wireless service provider that is associated with the phone number for a smartphone or other mobile device, and can send a message with a single function call. Messages can be delivered directly to the service provider's gateway, or can be relayed through a local mail server. With this API, an application can send text message alerts when certain conditions occur (such as an error) or as a notification mechanism that's used in addition standard email messages.

Time Protocol

The Time Protocol library provides an interface for synchronizing the local system's time and date with that of a server. The library enables developers to query a server for the current time and then update the system clock if desired.

Whois Protocol

The Whois protocol library provides an interface for requesting information about an Internet domain name. When a domain name is registered, the organization that registers the domain must provide certain contact information along with technical information such as the primary name servers for that domain. The Whois protocol enables an application to query a server which provides that registration information. The SocketTools library provides an API for requesting that information and returning it to the program so that it can be displayed or processed.

Application Storage Service

The Web Services library provides a private cloud storage API for uploading and downloading shared data files which are available to your application. This is primarily intended for use by developers to store configuration information and other data generated by the application. For example, you may want to store certain application settings, and the next time a user or organization installs your software, those settings can be downloaded and restored.

The connection to the storage service is always secure, using TLS 1.2 and AES-256 bit encryption. There are no third-party services you need to subscribe to, and there are no additional usernames or passwords for you to manage. Access to the service is associated with an account which is created when you purchase a development license, and the security tokens are bound to the runtime license key used when initializing the API. You also have the option to compress and encrypt your data you store using the [Encoding, Compression and Encryption](#) APIs.

Terminology

When you get started with the storage API, you'll notice there is some different terminology which is used. This will provide an overview of that terminology, and compare it to common terms used with traditional protocols like FTP. When accessing an FTP server, you generally deal with *directories*, *files*, *names* and *types* (generally whether the file is binary or text). The storage API has similar concepts, but uses somewhat different terminology.

Application Identifiers

An application identifier (AppId) is a null terminated string which uniquely identifies your application. This string, used in conjunction with your runtime license key, is used to generate an access token. This token is used to access the storage container which contains the data which you've stored.

It is recommended you use a standard format for the AppId which consists of your company name, application name and optionally a version number. Some examples of an AppId string would be:

- MyCompany.MyApplication
- MyCompany.MyApplication.1

It is important to note with these two example IDs, although they are similar, they reference two different applications. Objects stored using the first ID will not be accessible using the second ID. If you want to store objects which should be shared between all versions of the application, it is recommended you use the first form, without the version number. If you want to store objects which should only be accessible to a specific version of your application, then it is recommended you use the second form which includes the version number.

The AppId must only consist of ASCII letters, numbers, the period and underscore character. Whitespace characters and non-ASCII Unicode characters are not permitted. The maximum length of the string is 64 characters, including the terminating null character. It is not required for your application to create a unique AppId. Each storage account has a default internal AppId named **SocketTools.Storage.Default**. This AppId is used if a NULL pointer or an empty string is specified.

Containers

Storage containers are somewhat analogous to directories or folders in a file system, however they are general purpose and designed to allow you to control how your application accesses the data that's been stored. There are four container types which are defined by the API, and you can think of them as types of boxes or file cabinets which you store your data in.

It is important to keep in mind these containers are available to all users of your application, your program controls who has access to any particular data file. Your users will not be able to "browse" any of the containers unless you specifically provide that capability by implementing it in your own code. There is no public access to any of the data which you upload, and our service does not use an open API accessible by third parties.

WEB_STORAGE_GLOBAL

The global storage container which is available to all users of your application. Any data stored in this container is available to everyone who uses your software. Unless you have a specific need to limit access to the data to a specific user or group of users, this is the recommended container you use to store data.

WEB_STORAGE_DOMAIN

The domain storage container is limited to users in the same local domain, defined either by the name of the domain or workgroup assigned to the computer system. This can provide a kind of organization wide storage, but it does depend on the domain being unique. For example, if you are using domain storage for your application, and you have multiple customers who have systems part of the default "Workgroup" domain, they would all share the same container. If the domain or workgroup name changes, then data stored in the container would no longer be available.

WEB_STORAGE_MACHINE

The local machine storage container is associated with the physical computer system your application is running on. The machine is identified by unique characteristics of the system, including the boot volume GUID. Data stored in this container can only be accessed from the application running on that particular system. If the operating system is reinstalled, the machine ID will change and data stored in this container would no longer be available.

WEB_STORAGE_USER

The current user storage container is associated with the current user who is using your application. The user identifier is based on the Windows Security Identifier (SID) assigned to the account when it's created. If the user account is deleted, the data stored in this container will no longer be available to the application. Another user on the same computer system would not be able to access the data in this container.

If you decide to use anything other than global storage, the data your application stores can be orphaned if the system configuration or user account changes. It's recommended you store critical application data and general configuration information using **WEB_STORAGE_GLOBAL** and use other non-global storage containers for configuration information which is unique to that system and/or user which is not critical and can be easily recreated. If you're concerned about protecting the data you upload to global storage, you can encrypt it prior to storing it.

Objects

Storage objects are similar to files in a file system. They are discrete blocks of data, associated with a label (name), have attributes and are associated with a particular content type. However, an object does not need to be an actual file on the local system. For example, you could store an object which is a string, a pointer to a structure, or any block of memory. You could also just store a complete file as an object. Unlike files, you cannot perform partial reads of an object or "seek" into certain parts of a stored object. Of course, you can download an object, either in memory or to a local file, and perform whatever operations you require on the data.

Labels

Object labels are similar to file names, and are a way to identify a stored object instead of using its internal object ID. However, there are some important differences. The most significant difference

being labels are case-sensitive, unlike Windows file names. An object with the label "AppConfig" is considered to be different than one with the label "appconfig". Labels can contain Unicode characters, but they cannot contain control characters.

You can also use forward slashes or backslash characters in the label, but it's important to note objects are not stored in a hierarchical structure. Your application can store objects using a folder-like structure, but it's not something which is enforced by the API.

Media Type

Each object your application stores is associated with a media type (also called a content type) which identifies the object's data. This uses the standard MIME media type designations, such as "text/plain" or "application/octet-stream". Your application can explicitly specify the media type you want to associate with the object, or you can have the API choose for you, based on the contents of the object and using the label as a hint for what it may contain. For example, if you create an object with the label "AppConfig.xml" and it contains text, then the API will select "text/xml" as the default media type.

Initialization

The first step your application must take is to initialize the library and then open a storage container. The following functions are available for use by your application:

[WebInitialize](#)

Initialize the library for the current process. This must be the first function call the application makes before calling the other service API functions.

[WebOpenStorage](#)

Opens a storage container for your application and returns a handle which is used with other functions.

[WebCloseStorage](#)

Close the storage container and release the resources allocated for the session.

[WebUninitialize](#)

Release all resources which have been allocated for the current process. This is the last function call the application should make prior to terminating.

Data Storage

The library provides functions to upload and download to the storage container. You can store local files, or you can create objects from data in memory. There are also functions which make it easier to store and retrieve textual data using null terminated strings.

[WebGetFile](#)

Download the object data and store in a file on the local system. There is also an extended version of the function named [WebGetFileEx](#) which provides additional options, such as the ability to retrieve information about the object downloaded in a single function call.

[WebGetObject](#)

Download the object data and store it in a memory buffer provided by the caller. The buffer can either be a pre-allocated block of memory, or reference a global memory handle which will contain the data when the function returns.

[WebGetTextObject](#)

Download the object data and store it in a null terminated string. This function would be used with data which is only textual, and it may contain Unicode text. If the the Unicode version of the function is called, the text is automatically converted from UTF-8 encoded to UTF-16 encoded text.

[WebPutFile](#)

Upload the contents of a local file and store it as an object in the current container. There is also an extended version of the function named [WebPutFileEx](#) which provides additional options, such as specifying the object attributes, media type and information about the stored object when the function returns.

[WebPutObject](#)

Upload the object data from a buffer in memory and store it as an object in the current container. This function would typically be used to store binary data, including compressed or encrypted text.

[WebPutTextObject](#)

Upload the contents of a string and store it as an object in the current container. The text is specified as a null terminated string, and if the Unicode version of the function is used, the text will be converted and stored as UTF-8 encoded text. The [WebGetTextObject](#) function will automatically convert the text back to UTF-16 encoding when the text object is retrieved from storage.

Data Management

The data management functions allow you to obtain information about stored objects and perform typical operations such as copying, renaming and deleting objects from the container.

[WebGetObjectInformation](#)

Returns information about a specific object stored in the container. This function populates a [WEB_STORAGE_OBJECT](#) structure which will contain metadata for the object such as its ID, size, attributes, creation and modification times.

[WebGetFirstObject](#)

Enables your application to search for and enumerate objects in a container based on their label and/or their media type. This function is used in conjunction with the [WebGetNextObject](#) function to list all matching objects in a container.

[WebCompareFile](#)

Compares the contents of a local file with the data in a stored object. This function can be used to determine if the contents of a file have changed since the file was previously stored using the [WebPutFile](#) function.

[WebCompareObject](#)

Compares the contents of data in memory with the data in a stored object. This function can be used to determine if the contents of the buffer have changed since the data was previously stored using the [WebPutObject](#) function.

[WebCompareText](#)

Compares the contents of null terminated string with the text in a stored object. This function can be used to determine if the contents of the string have changed since the data was previously stored using the [WebPutTextObject](#) function. If the Unicode version of this function is used, the string is automatically converted to use UTF-8 encoding prior to being compared with the contents of the stored object.

[WebCopyObject](#)

Copies the contents of a stored object to a new container, or duplicating the object within the same container using a different label. Information about the newly created object is returned to the caller.

[WebMoveObject](#)

Moves the contents of a stored object to a new container. Information about the object which has been moved will be returned to the caller.

[WebRenameObject](#)

Changes the label associated with a stored object. The new label for the object cannot already exist in

the same container. If you want to change the label to one already assigned to an existing object, the object must first be deleted.

[WebDeleteObject](#)

Removes the stored object from the container. This operation is immediate and permanent. Deleted objects cannot be recovered by the application at a later time.

[WebGetStorageQuota](#)

Returns information about how much storage space is available. It will populate a `WEB_STORAGE_QUOTA` structure which will specify how many bytes of storage you're using and how many objects you have created. It is important to note accounts created with an evaluation license have much lower quota limits than a standard account and should be used for testing purposes only. After the evaluation period has ended, all objects stored using the evaluation license will be deleted.

[WebResetStorage](#)

Resets the storage container and deletes all objects which were stored there. This function resets the container back to its initial state, deleting all object metadata from the database and removing all stored data. This operation is immediate and the objects stored in the container are permanently deleted. They cannot be recovered by your application.

Other Functions

Several additional utility functions are available as part of the storage API, including functions to register and de-register application identifiers and validate object labels.

[WebRegisterAppId](#)

Register a new application identifier (AppId) to be used to access a storage container. It is not required you create a unique application ID, but it can be helpful to distinguish stored content between different versions of your applications.

[WebUnregisterAppId](#)

Unregister an application identifier which was previously registered by your application. You should be extremely careful when using this function because it permanently delete all stored objects created using the AppId value. Internally it revokes the access token granted to your application and causes the server to expunge all objects in the container associated with the token.

[WebValidateAppId](#)

A utility function which can be used to validate an application identifier, ensuring it is valid and has been registered.

[WebValidateLabel](#)

A utility function which can be used to validate an object label to ensure it does not contain any invalid characters. This would be primarily used by applications which allow a user to specify the label names for the objects being stored.

Domain Name Service

The Domain Name Service (DNS) protocol is what applications use to resolve domain names into Internet addresses, as well as provide other information about a domain, such as the name of the mail servers which are responsible for receiving email for users in that domain. All of the SocketTools libraries provide basic domain name resolution functionality, but the Domain Name Services library gives an application direct control over what servers are queried, the amount of time spent waiting for a response and the type of information that is returned.

The first step that your application must take is to initialize the library and then create a handle for the client session. Unlike many of the other libraries, there are no connection related functions because DNS uses UDP datagrams rather than TCP streams. The following functions are available for use by your application:

[DnsInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other DNS API functions.

[DnsCreateHandle](#)

Create a handle that is used by the library to reference the client session. There are two arguments, a timeout period and a retry count. These values are used together to determine the total amount of time that the library will take in an attempt to resolve a hostname or IP address. The default values of 15 seconds and 4 retries are recommended for most applications.

[DnsCloseHandle](#)

Release the handle that was previously created by the call to **DnsCreateHandle**. Any memory allocated by the library on behalf of the application is released and the datagram socket that was created is closed.

[DnsRegisterServer](#)

Specify a nameserver that the library should use to resolve queries. By default, the library will use the nameservers that the local host was configured to use. This function enables you to override that default and specify your own servers, independent of the system's configuration.

[DnsUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Address Conversion

Internet Protocol (IP) addresses can be represented in one of two ways, either as unsigned 32-bit integer value or as string where each byte of the address is written as an integer value and separated by periods. For example, the local loopback IP address can either be specified as the string "127.0.0.1" or as the integer value 16777343. In most cases, using the string form of the address is easier; however, some functions require that the numeric value be used. The following functions are provided to enable you to convert between the two formats.

[DnsGetAddress](#)

Convert an IP address string in dotted notation into a 32-bit integer value.

[DnsFormatAddress](#)

Convert a numeric IP address into a string in dotted notation, copying the result into a buffer that you provide to the function.

Host Tables

When resolving a host name or IP address, the library will first search the local system's host table, a file that is used to map host names to addresses. On Windows 95/98 and Windows Me, if the file exists it is usually found

in C:\Windows\hosts. On Windows NT and later versions, it is found in C:\Windows\system32\drivers\etc\hosts. Note that the file does not have an extension.

[DnsGetDefaultHostFile](#)

Return the full path of the file that contains the default host table for the local system. This can be useful if you wish to temporarily switch between the default host file and another host file specific to your application.

[DnsGetHostFile](#)

Return the full path of the host table that is currently being used by the library. Initially this is the same as the default host table for the local system.

[DnsSetHostFile](#)

Specify a new host table which the library should use to resolve host names and IP addresses. This can be used by an application to provide its own local cache of host names and addresses in order to speed up the process of host name resolution.

Host Name Resolution

The library can be used to resolve host names into IP addresses, as well as perform reverse DNS lookups converting IP addresses into the host names that are assigned to them. The library will search the local system's host table first, and then perform a nameserver query if required.

[DnsGetHostAddress](#)

Resolve a host name into an IP address, returned as a string in dotted notation. The library first checks the system's local host table, and if the name is not found there, it will perform a nameserver query for the A (address) record for that host.

[DnsGetHostName](#)

Resolve an IP address into a host name. The address is passed as a string in dotted notation, and the fully qualified host name is returned in a string buffer you provide to the function. The library first checks the system's local host table, and if the address is not found there, it will perform a nameserver query for the PTR (pointer) record for that address.

Mail Exchange Records

When a system needs to deliver a mail message to someone, it needs to determine what server is responsible for accepting mail for that user. This is done by looking up the mail exchange (MX) record for the domain. For example, if a message was addressed to joe@example.com, to determine the name of the mail server that would accept mail for that recipient, you would perform an MX record query against the domain example.com. A domain may have more than one mail server, in which case multiple MX records will be returned.

[DnsEnumMailExchanges](#)

Enumerate all of the mail exchanges for the specified domain. If there are multiple servers, they may be prioritized so that certain servers are given precedence over the others. This function will return the highest priority servers first in the list. Refer to the Technical Reference for an example of how this function can be used.

Advanced Queries

In addition to providing host name and IP address resolution, the library can be used to perform advanced queries for other types of records.

[DnsGetHostInfo](#)

Return additional information about the specified host name. If the name server has been configured to provide host information for the domain, this function will return that data. Typically it is used to indicate what hardware and operating system the host uses.

[DnsGetHostServices](#)

Return information about the UDP and TCP based services that the host provides. If defined, this will return a list of service names such as "ftp" and "http". Note that your application should not depend on this information to be a definitive list of what services a server provides.

[DnsGetRecord](#)

Perform a general nameserver query for a specific record type. This function can be used to perform queries for the common record types such as A and PTR records, as well as for other record types such as TXT (text) records. Refer to the Technical Reference for more information about the specific types of records that can be returned.

Encoding, Compression and Encryption

A common requirement for applications which use Internet protocols is the need to encode binary files, as well as compress data to reduce the bandwidth and time required to send or receive the data. Encoding a binary file converts the contents of the file into printable characters which can be safely transferred over the Internet using protocols that only support a subset of 7-bit ASCII characters. This is commonly a restriction for email, since many mail servers still are not capable of correctly processing messages which contain control characters, 8-bit data or multi-byte character sequences found in International text.

To address this problem, the sender encodes and sends the data as part of a message; the recipient then extracts and decodes the data, with the end result being the same as the original, without any potential corruption by the mail servers which store and/or forward the message. The File Encoding library supports several encoding and decoding methods, including standard base64 encoding, quoted-printable encoding and uuencoding. For applications which access USENET newsgroup, the library also supports the newer yEnc encoding method which has become a popular method for attaching binary files to a message.

This library also can be used to compress files, reducing their overall size. Two compression algorithms are supported, the standard deflate algorithm which is commonly used in Zip files, and an algorithm based on the Burrows-Wheeler Transform (BWT) which can offer improved compression over the deflate algorithm for some types of files. The developer has control over the type of compression performed, as well as details such as the level of compression which determines how much memory and CPU time is allocated to compress the data. Developers can even create their own custom compression formats by creating an application-specific header block, typically represented by a structure or user-defined type that can be used to provide information to the program.

Unlike the other SocketTools libraries, there are no initialization functions for this library, and there are no handles used. All operations are performed either on files or on memory buffers provided by the application. The library is split into two general areas of functionality. The first group of functions enables you to encode and decode binary files and the second group enables you to compress and expand data.

Note that if you are interested in using this library for purposes of attaching files to an email message, it is not necessary that you use these functions. The [Mail Message](#) library has the ability to automatically encode and decode file attachments without requiring that you use the functions in this library. However, the File Encoding library is useful if you need the ability to encode, compress and/or encrypt data for use in other applications.

Encoding Types

There are several different encoding types available, with the default being the standard MIME encoding called Base64. The following encoding methods are supported by the library:

Base64

Base64 encoding works by representing three bytes of data as four printable characters. Each of the three bytes is converted into four six-bit numbers, and each six-bit number is converted to one of 64 printable characters (which is where the encoding method gets its name). Base64 is the default encoding method used by the library and is the standard encoding used for MIME formatted email messages as well as many other applications.

Quoted-Printable

Quoted-printable encoding is primarily used in email messages, and is best used when the data being encoded is text which consists primarily of printable characters. Only characters with the high-bit set or a certain subset of printable characters are actually encoded by representing them as their hexadecimal value. All other printable characters are passed through unmodified.

Uuencode

One of the original encoding methods used for email, it gets its name from two UNIX command-line utilities called uuencode and uudecode, which were used to encode and decode files. Like Base64, uuencoding converts three bytes of data into four six-bit numbers, and then a value of 32 is added to ensure that it is printable. Uuencoding also adds some additional characters which are used to ensure the integrity of the encoded data. This encoding method is still used when posting files to USENET newsgroups, but has largely been replaced by Base64 when attaching files to email messages.

yEnc

yEnc is an encoding method that was created specifically for binary newsgroups on USENET. Because USENET doesn't have the same limitations as email systems in terms of what kind of characters can be safely used, yEnc only encodes null characters and certain control characters; the remaining 8-bit data is passed through as is which can significantly reduce the overall size of the encoded data. yEnc also uses checksums to ensure the integrity of the data and is designed so that a large file can be split across multiple messages and then recreated.

Data Encoding

Encoding a binary file converts the contents of the file into printable characters which can be safely transferred over the Internet using protocols that only support a subset of 7-bit ASCII characters. This is commonly a restriction for email, since many mail servers still are not capable of correctly processing messages which contain control characters, 8-bit data or multi-byte character sequences found in International text. To address this problem, the sender encodes and sends the data as part of a message; the recipient then extracts and decodes the data, with the end result being the same as the original, without any potential corruption by the mail servers which store and/or forward the message.

EncodeFile

This function encodes a file using the specified encoding method, storing the encoded data in a new file. An option also allows you to automatically compress the data prior to encoding it in order to reduce the overall size of the encoded file.

DecodeFile

This function decodes a previously encoded file using the specified encoding method, restoring the original contents. If the encoded data was compressed, this function can also be used to automatically expand the data after it has been decoded.

EncodeBuffer

This function encodes a block of data in memory using the specified encoding type. This is similar to the **EncodeFile** function, except that instead of using disk files, all of the encoding is done in memory. As with encoding a file, you can also specify that you want the data to be compressed prior to being encoded.

DecodeBuffer

This function decodes a previously encoded block of data. This is similar to the **DecodeFile** function, except that instead of using disk files, all of the decoding is done in memory. As with decoding a file, you can also specify that you want compressed data to be automatically expanded after it has been decoded.

IsUnicodeText

This function can be used to check the contents of a string to ensure that it contains valid UTF-8 or UTF-16 encoded Unicode text. One of the primary uses of the function is to determine if data received over the network uses valid UTF-8 character encoding. The **UnicodeDecodeText** function can then be used to convert it to UTF-16 or multi-byte text.

UnicodeDecodeText

This function decodes UTF-8 encoded text and returns the decoded text in a string provided by the

caller. It can be used to convert UTF-8 text to UTF-16, or to localized multi-byte text. It is similar to the **MultiByteToWideChar** function, but performs some additional checks to ensure the encoded text is valid and can be safely decoded.

[UnicodeEncodeText](#)

This function encodes a multi-byte or Unicode string as UTF-8 encoded text. It is similar to the **WideCharToMultiByte** function and ensures Unicode text is normalized prior to being encoded.

Data Compression

In addition to encoding and decoding data, the library can be used to compress data in order to reduce its size. The compression functions may be used separately, or may be used as part of the process of encoding a file or a block of data.

[CompressFile](#)

This function reduces the size of a file using the standard Deflate algorithm. This is the same algorithm that is commonly used in Zip archives. Note however, that this does not create a Zip file, it simply uses the same compression method.

[ExpandFile](#)

This function restores the original contents of a file that was previously compressed using the **CompressFile** function. Note that this function is not designed to extract files from a Zip archive or expand data compressed using a different algorithm.

[CompressBuffer](#)

This function uses the Deflate algorithm to reduce the size of a block of data. This is similar to the **CompressFile** function except that it performs the compression on data in memory rather than in a disk file.

[ExpandBuffer](#)

This function restores the data that was previously compressed using the **CompressBuffer** function.

There are some additional functions for compressing files that provide more advanced options such as the ability to specify the compression type and level, as well as enabling you to create your own custom file compression formats. Please refer to the Technical Reference for more information.

Data Encryption

There are several functions which provide a simplified interface for encrypting and decrypting data using the AES-256 Advanced Encryption Standard algorithm.

[AesEncryptFile](#)

This function encrypts the contents of a file. A password string can be provided which is used to generate the encryption key. To encrypt data stored in memory, use the **AesEncryptBuffer** function.

[AesDecryptFile](#)

This function is used to decrypt the contents of a file that was previously encrypted using **AesEncryptFile**.

[AesEncryptBuffer](#)

This function is used to encrypt the contents of a buffer in memory. The encrypted data is returned in a buffer that is provided by the caller. The encrypted data will be in a binary format which can contain embedded null bytes. If you need to encrypt string values, it's recommended you use the **AesEncryptString** function.

[AesDecryptBuffer](#)

This function is used to decrypt a buffer in memory that was previously encrypted using **AesEncryptBuffer**.

AesEncryptString

This function is used to encrypt a null terminated string and the encrypted data is returned as base64 encoded text. This is similar to the **AesEncryptBuffer** function, but it is designed to work specifically with strings and the encrypted output can be safely stored as a text value by the application.

AesDecryptString

This function is used to decrypt a string that was previously encrypted using **AesEncryptString**.

The encryption functions use the Microsoft CryptoAPI and the RSA AES cryptographic provider. This provider may not be available in some languages, countries or regions. It is important to note the availability of this provider may also be constrained by cryptography export restrictions imposed by the United States or other countries.

File Transfer Protocol

The File Transfer Protocol (FTP) is the most common application protocol used to upload and download files between a local system and a server. In addition to basic file transfer capabilities, FTP also enables a client application to perform common file and directory management functions on the server, such as renaming and deleting files or creating new directories. The SocketTools Library Edition also supports secure file transfers using SSH (SFTP) and TLS (FTPS) by simply specifying an option when establishing the connection.

The first step that your application must take is to initialize the library and then establish a connection. The following functions are available for use by your application:

[FtpInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other FTP API functions.

[FtpConnect](#)

Connect to the server, using either a host name or IP address. The function has several options related to security as well as the general operation of the library. One important option is `FTP_OPTION_PASSIVE`, which instructs the library to use passive mode file transfers. If the local system is behind a firewall or a route which uses Network Address Translation (NAT), it is often necessary to use this option. This function returns a client handle which is used in subsequent calls to the library.

[FtpProxyConnect](#)

A variation on the standard connection, this function can be used to connect to an FTP server through a proxy server. The library provides support for a number of standard proxy types, such as those used by the Gauntlet and InterLock proxy servers. A custom proxy server type is also supported where your application can send any custom commands required to establish the connection.

[FtpLogin](#)

Authenticate the client session, providing the server with a user name, password and optionally an account name. It is also possible to use an anonymous (unauthenticated) session by providing empty strings as the username and password.

[FtpDisconnect](#)

Disconnect from the server and release the memory allocated for that client session. After this function is called, the client handle is no longer valid.

[FtpUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

File Transfers

The library provides several functions which can be used to transfer files between the local and server. This group of functions is high level, meaning that it is not necessary to actually write the code to read and/or write the file data. The library automatically handles the lower level file I/O and notifies your application of the status of the transfer by periodically generating progress events.

[FtpGetData](#)

This function transfers a file from the server to the local system, storing the file data in memory. This can be useful if your application needs to perform some operation based on the contents of the file, but does not need to store the file locally.

[FtpGetFile](#)

This function transfers a file from the server and stores it in a file on the local system. This function is similar to how the GET command works for the command-line FTP client in Windows.

[FtpGetMultipleFiles](#)

This function transfers multiple files from the server and stores them in a directory on the local system. A wildcard may be specified so that only files which a certain name or those that match a particular file extension are downloaded. This function is similar to how the MGET command works for the command-line FTP client in Windows.

[FtpPutData](#)

This function creates a file on the server containing the data that you provide. This can be useful if your application wants to upload dynamically created content without having to create a temporary file on the local system.

[FtpPutFile](#)

This function uploads a file from the local system to the server. This function is similar to how the PUT command works for the command-line FTP client in Windows.

[FtpPutMultipleFiles](#)

This function transfers multiple files from the local system to a directory on the server. A wildcard may be specified so that only files with a certain name or those that match a particular file extension are uploaded. This function is similar to how the MPUT command works for the command-line FTP client in Windows.

File Management

In addition to performing file transfers, the File Transfer Protocol library can also perform many of the same kinds of file management functions on the server as you would on the local system.

[FtpDeleteFile](#)

Delete a file from the server. This operation requires that the current user have the appropriate permissions to delete the file.

[FtpRenameFile](#)

Change the name of a file or move a file to a different directory. This operation requires that the current user have the appropriate permissions to rename the file. If the file is being moved to another directory, the user must have permission to access that directory.

[FtpGetFileStatus](#)

Return status information about the file in the form of a structure. This typically specifies the ownership, access permissions, size and modification time for the file. It is similar to opening a directory on the server and reading information about the file, but with less overhead.

[FtpGetFileSize](#)

Return the size of a file on the server without actually downloading the contents of the file.

[FtpGetFileTime](#)

Return the modification time for the specified file on the server. This can be used by you application to determine if the file has been changed since the time that you last uploaded or downloaded the contents.

[FtpSetFileTime](#)

Update the modification time for a file on the server. This function requires that the current user have the appropriate permissions to change the last modification timestamp for the file. Note that this is not supported on all servers and in some cases may be restricted to specific accounts.

[FtpGetFilePermissions](#)

Return the access permissions for a file on the server. This can be used to determine if a file can be read, modified and/or deleted by the current user. For users who are familiar with UNIX file permissions, it is the same type which is used by the library.

[FtpSetFilePermissions](#)

Change the access permissions for a file. This function is supported on most UNIX based servers, as well as any other server that supports the site-specific CHMOD command.

Directory Management

The library also provides a set of functions which can be used to access and manage directories or folders, including the ability to list and search for files, create new directories and remove empty directories from the server.

[FtpOpenDirectory](#)

Open the specified directory on the server. This is the first step in returning a list of files in the directory. After the directory has been opened, information about the files it contains can be returned to the application. The directory path may also include wildcards to only return information about a certain subset of files based on the file name or extension.

[FtpGetFirstFile](#)

Return information about the first file in the directory that has been opened. This is similar to how the Windows API function **FindFirstFile** works.

[FtpGetNextFile](#)

Return information about the next file in the directory that has been opened. This function is called repeatedly until it indicates that all of the files have been returned. This is similar to how the Windows API function **FindNextFile** works.

[FtpChangeDirectory](#)

Change the current working directory on the server. This is similar to how the CD command is used from the command-line to change the current directory in Windows. If a path is not specified in the file name, the current working directory is where files will be uploaded to and downloaded from.

[FtpCreateDirectory](#)

Create a new directory on the server. This requires that the current user have the appropriate access permissions in order to create the directory.

[FtpRemoveDirectory](#)

Remove an empty directory from the server. This operation requires that the current user have the appropriate permissions to delete the directory. For safety, it is required that the directory does not contain any files or subdirectories or the operation will fail.

GeoIP Location Service

The Web Services library provides an API for obtaining geographical information about the physical location of the computer system based on its external IP address. This can enable developers to know where their application is being used, and provide convenience functionality such as automatically completing a form based on the location of the user.

The connection to the location service is always secure and does not require you subscribe to any third-party services. The accuracy of this information can vary depending on the location, with the most detailed information being available for North America. The country and time zone information for all locations is generally accurate. However, as the location information becomes more precise, details such as city names, postal codes and specific geographic locations (e.g.: longitude and latitude) may have reduced accuracy.

Software which is designed to protect the privacy of users, such as those which route all Internet traffic through proxy servers or VPNs, can significantly impact the accuracy of this information. In this case, the data returned in this structure may reflect the location of the network or proxy server, and not the location of the person using your application. It is recommended you always request permission from the user before acquiring their location, have them confirm the location is correct and provide a mechanism for them to update the information.

Functions

To obtain the location of the local computer system, use the following functions:

[WebInitialize](#)

Initialize the library for the current process. This must be the first function call the application makes before calling the other service API functions.

[WebGetLocation](#)

This function populates a [WEB_LOCATION](#) structure which contains information about the physical location of the system. This structure has a number of members which provide details about the location:

Member	Description
szLocationId	A string which contains contains a string of hexadecimal characters which uniquely identifies the location for this computer system. This value is used internally by the location service, and may also be used by the application for its own purposes.
szIPAddress	A string which contains the external IP address for the local system. If the system has been assigned multiple IP addresses, it reflects the address of the interface used to establish the connection with the location server.
nAutonomousSystemNumber	An integer which is used to uniquely identify a global network (autonomous system) which is connected to the Internet. This value can be used to determine the ownership of a particular network.
szOrganization	A string which identifies the organization associated with the local system's external IP address. For residential end-users this is typically the name of their Internet Service provider, however it may also identify a private company.
szRegionName	A string which identifies a broad geographical area, such

	as "North America" or "Southeast Asia".
nRegionCode	An integer which identifies the geographical region. This value corresponds to standard UN M49 region codes.
szCountryName	A string which contains the full name of the country in which the external IP address is located, such as "United States". These names will always be in English, regardless of the current system locale.
szCountryAlpha2	A string which contains the ISO 3166-1 alpha-2 code assigned to the country. For example, the alpha-2 code for the United States is "US".
szCountryAlpha3	A string which contains the ISO 3166-1 alpha-3 code assigned to the country. For example, the alpha-3 code for the United States is "USA".
nCountryCode	An integer value which identifies the country using the standard UN country code. For example, the numeric country code for the United States is 840.
szSubdivision	A string which identifies a geopolitical subdivision within a country. In the United States, this will contain the full name of the state or commonwealth. In Canada, this will contain the name of the province or territory.
szSubdivisionCode	A string which is either a two- or three-letter code which identifies a geopolitical subdivision within the country. These codes are defined by the ISO 3166-2 standard. For example, the code for the state of California in the United States is "CA".
szCityName	A string which identifies the city at this location. These names will always be in English, regardless of the current system locale. If the city name cannot be determined, this member may contain an empty string.
szPostalCode	A string which contains the postal code associated with the location. In the United States, this is a 5-digit numeric code. Local delivery portions of a postal code (such as the ZIP+4 code in the United States) are not included.
szCoordinates	A string which specifies the location expressed using the Universal Transverse Mercator (UTM) coordinate system with the WGS-84 ellipsoid. These coordinates are commonly used with the Global Positioning System (GPS).
szTimezone	A string which specifies the full time zone name. These names are defined by the Internet Assigned Numbers Authority (IANA) and have values like "America/Los_Angeles" and "Europe/London".
szTzShortName	A string which specifies the abbreviated time zone code. If daylight savings time is used within the time zone, then this value can change based on whether or not daylight savings is in effect. If a short time zone code cannot be

	determined, a value such as "UTC+9" may be returned, indicating the number of hours ahead or behind UTC.
nTimezoneOffset	A integer which specifies the number of seconds east or west of the prime meridian (UTC). A positive value indicates a time zone which is east of the prime meridian and a negative value indicates a time zone which is west of the prime meridian.
dLatitude	A real number which specifies the latitude of the location in decimal format. A positive value indicates a location which is north of the equator, while a negative value is a location which is south of the equator.
dLongitude	A real number which specifies the longitude of the location in decimal format. A positive value indicates a location which is east of the prime meridian, while a negative value is a location which is west of the prime meridian.
stLocalTime	A SYSTEMTIME structure which contains information about the current date and time at the location, adjusted for its time zone and whether or not it's in daylight savings time.

[WebUninitialize](#)

Release all resources that were allocated for the current process. This is the last function call the application should make prior to terminating.

Hypertext Transfer Protocol

The Hypertext Transfer Protocol (HTTP) is the most prevalent application protocol used on the Internet today. It was originally used for document retrieval, and has grown into a complex protocol which supports file uploading, script execution, file management and distributed web authoring through extensions such as WebDAV. The SocketTools Hypertext Transfer Protocol library implements version 0.9, 1.0 and 1.1 of the protocol, including features such as support for proxy servers, persistent connections, user-defined header fields and chunked data.

File Transfers

Similar to the API used with the File Transfer Protocol library, you can use HTTP to upload and download files. In addition to the standard method for downloading files, the library supports two methods for uploading files, using either the PUT or the POST command. When downloading a file from the server, you can either store the contents in a local file, or you can copy the data into a memory buffer that you allocate. Similarly, when uploading files, you can either specify a local file to upload, or you can provide a memory buffer that contains the file data to send to the server. High level functions such as **HttpPutFile** and **HttpGetFile** can be used to transfer files in a single function call. There are also functions such as **HttpOpenFile** and **HttpCreateFile** which provide lower level file I/O interfaces.

Script Execution

Another common use for HTTP is to execute scripts on the web server. The application can pass additional data to the script, which is similar in concept to how arguments are passed to a command that is entered from the command prompt. This typically uses the standard GET and POST commands, and the resulting output from the script is returned back to the application where it can be displayed or processed. There are several different functions you can use, depending on the service you're requesting information from. The **HttpPostData** function is general-purpose and can be used with virtually any type of POST request, including submitting binary data. However, it can require some additional settings such as the content type and encoding method. The **HttpPostJson** and **HttpPostXml** functions are specifically designed for requests which require JSON or XML payloads, respectively.

Uniform Resource Locators

Anyone who has used a web browser is familiar with the Uniform Resource Locator (URL); it is the value that is entered as the address of a website. URLs have a specific format which provides information about the server, the port number and the name of the resource that is being accessed:

[http|https]://[*username* : [*password*] @] hostname [:*port*] / resource [? *parameters*]

The first part of the URL identifies the protocol, also known as the scheme, which will be used. With web servers, this will be either http or https for secure connections. If a username and password is required for authentication, this can be included in the URL before the name of the server. Next, there is the name of the server to connect to, optionally followed by a port number. If no port number is given, then the default port for the protocol will be used. This is followed by the resource, which is usually a path to a file or script on the server. Parameters to the resource may also be specified, called the query string, which are typically used as arguments to a script that is executed on the server.

Understanding how a URL is constructed will help in understanding how the different functions in the library work together. For example, the server name and port number portion of the URL are the values passed to the **HttpConnect** function to establish the connection. The user name and password values are passed to the **HttpAuthenticate** function to authenticate the client session. And the resource name is passed to the **HttpGetData** or **HttpGetFile** functions to transfer it to the local system.

The first step that your application must take is to initialize the library and then establish a connection. The following functions are available for use by your application:

[HttpInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other HTTP API functions.

[HttpConnect](#)

Establish a connection to the server. This function will return a handle to a client session which is used in subsequent calls to the HTTP API.

[HttpProxyConnect](#)

A variation on the standard connection, this function can be used to connect to an HTTP server through a proxy server. The library provides support for standard CERN type proxies as well as tunneling proxies that are commonly used with secure TLS connections.

[HttpAuthenticate](#)

If the server requires the client to authenticate prior to accessing a resource, this function can be called to provide the user name and password. This is commonly used to restrict access to certain areas of a website to authenticated users only. Although it is permitted to authenticate immediately after connecting to a server, it is not required. An application can wait until the server returns an error indicating that authentication is required to access the resource. It can call this function at that time, and then re-request the resource. This is how most browsers work. This function may be called more than once during a session if the client needs to change the current user name and/or password being used to authenticate access to the server.

[HttpDisconnect](#)

Disconnect from the server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

[HttpUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

File Transfers

Using an API similar to the File Transfer Protocol library, this library provides several functions which can be used to transfer files between the local and server. This group of functions is high level, meaning that it is not necessary to actually write the code to read and/or write the file data. The library automatically handles the lower level file I/O and notifies your application of the status of the transfer by periodically generating progress events.

[HttpGetData](#)

This function transfers a file from the server to the local system, storing the file data in memory. This can be useful if your application needs to perform some operation based on the contents of the file, but does not need to store the file locally.

[HttpGetFile](#)

This function transfers a file from the server and stores it in a file on the local system.

[HttpPutData](#)

This function creates a file on the server containing the data that you provide. This can be useful if your application wants to upload dynamically created content without having to create a temporary file on the local system.

[HttpPutFile](#)

This function uploads a file from the local system to the server using the PUT command. Not all

servers support this command, and some may require that the client authenticate prior to calling this function.

[HttpPostFile](#)

This function uploads a file from the local system to the server using the POST command. This enables your application to upload a file in the same way that a user would when using a form in a web browser.

File Management

The library can also perform some basic file management functions as well as send custom commands to the server. Some web servers also provide more advanced document management functions using WebDAV, an extension to HTTP for distributed document authoring.

[HttpGetFileSize](#)

Return the size of a file on the server without actually downloading the contents of the file. It is important to note that most servers will only return file size information for actual documents stored on the server, not for dynamically created content generated by scripts or web pages which use server-side includes.

[HttpGetFileTime](#)

Return the modification time for the specified file on the server. This can be used by your application to determine if the file has been changed since the time that you last uploaded or downloaded the contents.

[HttpDeleteFile](#)

Remove a file from the server. This operation requires that the current user have the appropriate permissions to delete the file. Not all servers support the use of this command, and it would typically require that the client authenticate prior to calling this function.

[HttpCommand](#)

This function enables the client to send any command directly to the server. This is commonly used to issue custom commands to servers that are configured to use extensions to the standard protocol.

Script Execution

The library also provides functions to execute server-side scripts, returning the output back to your application. Your program can pass additional data to the script, typically either as a query string or as form data, which is similar in concept to how arguments are passed to a command that is entered from the command prompt.

[HttpGetData](#)

In addition to being used to simply return the contents of a file, this function can also be used to execute a script on the server and return the output of that script to your program. Arguments to the script can be specified by passing them as a query string. For example, consider the following resource which is a PHP script:

```
/app/test.php?data1=value1&data2=value2
```

This would specify that the script `/app/test.php` is to be executed, and two arguments will be passed to that script: `data1=value` and `data2=value2`. The ampersand is used to separate the arguments, and they are grouped as pairs of values separated by an equal sign. Note that the actual format and value of the query string depends on how the script is written.

[HttpPostData](#)

An alternative method of providing information to a script is to post data to the script. Instead of the data being part of the resource name itself, posted data is sent separately and is provided as input to the script. This is the same method that is typically used when a user clicks the Submit button on a web-based form. This function requires the name of the script and the address of a buffer that

contains the data that will be posted. The resulting output from the script is returned to the caller in the same way that **HttpGetData** works.

[HttpPostJson](#) and [HttpPostXml](#)

These are specialized versions of the **HttpPostData** function which are designed to work with JSON and XML payloads. They will automatically set the correct content type and encoding for the request. If you are using the Unicode version of these functions, they will automatically convert the payload to standard UTF-8 encoding prior to submitting the data to the server. It is recommended you use these functions when accessing RESTful API services which expect JSON or XML requests.

[HttpSubmitRequest](#)

This is a high-level function which supports either a GET, PUT or POST request in a single function call. With this function, there is no need to explicitly connect to the server using **HttpConnect**. The entire transaction (i.e.: establishing the connection, submitting the request, processing the server response and then disconnecting) is handled automatically. If your application does not need to maintain a persistent connection to the server, using this function can eliminate a lot of boilerplate code which would otherwise be required.

Internet Control Message Protocol

The Internet Control Message Protocol (ICMP) library enables your application to send and receive ICMP echo datagrams. These are a special type of IP datagram which can be used to determine if a server is reachable, as well as determine the amount of time it takes for data to be exchanged with the local system. The ICMP library can also be used to trace the route that data takes from the local system to the server, which can be useful in determining why a connection to a particular system may be experiencing higher latency than normal.

The first step that your application must take is to initialize the library and then create a handle for the client session. Unlike many of the other libraries, there are no connection related functions because ICMP uses IP datagrams rather than TCP streams. The following functions are available for use by your application:

[IcmpInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other ICMP API functions.

[IcmpCreateHandle](#)

This function will return a handle to a client session which is used in subsequent calls to the ICMP API. It is only required that you call this function if you're using the lower level ICMP functions to send and receive ICMP echo datagrams. The higher level functions like **IcmpEcho** and **IcmpTraceRoute** do not require a handle.

[IcmpCloseHandle](#)

Release the handle that was previously created by the call to **IcmpCreateHandle**. Any memory allocated by the library on behalf of the application is released and the datagram socket that was created is closed.

[IcmpUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Ping and TraceRoute

To determine if a server is reachable, your application can send ICMP echo datagrams. You can also map the route between the local system and the server by sending a series of echo datagrams to each intermediate host. This is what the ping.exe and tracert.exe command line utilities do, and you can emulate that functionality in your own applications.

[IcmpEcho](#)

This is the simplest function you can use to send ICMP echo datagrams. Specify the server, the size of the ICMP datagram you want to send and the number of times you want to send it. The function will return if the operation was successful along with information such as the average number of milliseconds it took for the datagram to be returned by the server. Note that it is not required that you create a handle to use this function.

[IcmpTraceRoute](#)

This function will map the route that data packets take from your local system to a server. Whenever you send data over the Internet, that data is routed from one computer system to another until it reaches its destination. This function returns statistical information about each system that the data is routed through, and the latency between that system and the local host.

[IcmpSendEcho](#)

This is a lower level function that will send a single ICMP echo datagram. It can be used with applications that want to have more direct control over the process of how the datagrams are sent, and is typically used with asynchronous sessions.

IcmpRecvEcho

This is a lower level function that will receive a single ICMP echo reply datagram that was returned by the server. Typically this is used to receive datagrams that were sent in response to the **IcmpSendEcho** function. The **IcmpGetTripTime** function can be used after the function returns in order to check the amount of time it took to receive the datagram.

Internet Message Access Protocol

The Internet Message Access Protocol (IMAP) is an application protocol which is used to access a user's email messages which are stored on a mail server. However, unlike the Post Office Protocol (POP) where messages are downloaded and processed on the local system, the messages on an IMAP server are retained on the server and processed remotely. This is ideal for users who need access to a centralized store of messages or have limited bandwidth. The SocketTools IMAP library implements the current standard for this protocol, and provides functions to retrieve messages, create and manage mailboxes, and search for specific messages based on some user-defined search criteria.

The first step your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

[ImapInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other IMAP API functions.

[ImapConnect](#)

Establish a connection to the IMAP server. This function will return a handle to a client session which is used in subsequent calls to the IMAP API.

[ImapDisconnect](#)

Disconnect from the IMAP server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

[ImapLogin](#)

Authenticate yourself to the server using a username and password. This function should be called immediately after the connection has been established to the server.

[ImapUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Managing Mailboxes

One of the primary differences between the IMAP and POP3 protocol is that IMAP is designed to manage messages on the mail server, rather than downloading all of the messages and storing them on the local system. To support this, IMAP allows the client to maintain multiple mailboxes on the server, which are similar in concept to message folders used by mail client software. A mailbox can contain messages, and in some cases a mailbox can contain other mailboxes, forming a hierarchy of mailboxes and messages, similar to directories and files in a filesystem. A special mailbox named INBOX contains new messages for the user, and additional mailboxes can be created, renamed and deleted as needed. Here are the most important functions for managing mailboxes:

[ImapCheckMailbox](#)

Check the mailbox for any new messages which may have arrived. Because messages are managed on the server, it is possible for new mail to arrive during the client session.

[ImapCreateMailbox](#)

Create a new mailbox on the server with the specified name.

[ImapDeleteMailbox](#)

Delete a mailbox from the server. Most servers will only permit a mailbox to be deleted if it does not contain any mailboxes itself. Unlike deleting a message, which can be undeleted, deleting a mailbox is permanent.

[ImapExamineMailbox](#)

Once the session has been established and authenticated, a mailbox should be selected. This enables the client to manage the messages in that mailbox. This function selects the specified mailbox in read-only mode so that messages can be read, but not modified. To select the mailbox in read-write mode, use the `ImapSelectMailbox` function.

[ImapExpungeMailbox](#)

Remove all of the messages marked for deletion and return updated status information about the current mailbox.

[ImapGetFirstMailbox](#)

This function begins the process of enumerating the available mailboxes on the server, according to certain criteria provided to the function.

[ImapGetNextMailbox](#)

This function returns the next mailbox from the server, based on the criteria specified to the **ImapGetFirstMailbox** function. When all the mailboxes have been returned, this function will return an error indicating that there are no more mailboxes.

[ImapRenameMailbox](#)

Renames an existing mailbox. One of the interesting uses of this function is the ability to rename the special INBOX mailbox. Instead of actually renaming it, it moves all of the messages to the new mailbox and empties the INBOX.

[ImapSelectMailbox](#)

Once the session has been established and authenticated, a mailbox should be selected. Selecting a mailbox enables the client to manage the messages in that mailbox. This function selects the specified mailbox in read-write mode so that changes can be made to the mailbox.

[ImapUnselectMailbox](#)

This function unselects the currently selected mailbox, and allows the caller to specify if messages marked for deletion should be expunged (removed) from the mailbox or reset back to an undeleted state.

Managing Messages

There are functions in the IMAP library for managing messages which enables the application to create, delete and move messages. To use these functions, a mailbox must be selected, either by calling the **ImapSelectMailbox** or **ImapExamineMailbox** function. Functions which modify the mailbox require that it be opened in read-write mode. Messages are identified by a number, starting with one for the first message in the mailbox.

[ImapCopyMessage](#)

Copy a message to a specific mailbox.

[ImapDeleteMessage](#)

Mark the specified message for deletion. Unlike the POP3 protocol, when a message is deleted on an IMAP server it can still be accessed. The message will not actually be removed from the mailbox unless the mailbox is expunged, unselected or the client disconnects from the server.

[ImapEnumMessages](#)

Return information about all, or a specific range of, messages on the server.

[ImapGetMessageCount](#)

Return the number of messages in the currently selected mailbox.

[ImapGetMessageFlags](#)

Return the status flags for a specific message. Messages have a number of flags which can be set that determines their status in the mailbox. For example, messages can be flagged as answered, seen

(read), recent (new) or deleted.

[ImapGetMessageSize](#)

Return the size of the message in bytes.

[ImapSetMessageFlags](#)

Set one or more flags for the specified message. Flags can be cleared, added or replaced using this function.

[ImapUndeleteMessage](#)

Remove the deletion flag from the specified message.

Viewing Messages

One of the more powerful features of the IMAP protocol is the ability to precisely select what kinds of message data you wish to retrieve from the server. It is possible to retrieve only specific headers, or specific sections of a multipart message. Because IMAP understands MIME formatted messages, it is possible to only retrieve the textual portion of a message without having to download any attachments that may have come with it.

[ImapGetHeaderValue](#)

This function returns the value for a specified header field in the message. Using this function, it is not necessary to download and parse the message header. To obtain the value of a header field in a specific part of a multipart message, use the **ImapGetHeaderValueEx** function.

[ImapOpenMessage](#)

This is a lower level function which opens a message for reading from the server. A more complex version of this function called **ImapOpenMessageEx** function allows you to specify the type of message data that you want, a specific part of a multipart message, and a byte offset into the message. The application would then call **ImapRead** to read the contents of the message, followed by **ImapCloseMessage** when all the message data has been read. Also see the **ImapGetMessage** function, which will return the contents of a message into a memory buffer.

[ImapGetMessageParts](#)

This function returns the number of parts in a multipart message and is useful for determining if a message is a simple message or a MIME formatted message with multiple parts, such as one that includes file attachments.

Downloading Messages

In some cases, it may be preferable to download a complete message from the server to the local system. This can be easily done with a single function call.

[ImapGetMessage](#)

This function retrieves the specified message and stores it in a buffer provided by the caller; you can specify the type of message data that you want, a specific part of a multipart message and the amount of data that you want. For example, it is possible to request that only the first 1500 bytes of the body of the 3rd part of a multipart message should be returned.

[ImapStoreMessage](#)

This function downloads a complete message and stores it as a text file on the local system.

Mail Message

The Mail Message library can be used to create and process messages in the format defined by the Multipurpose Internet Mail Extensions (MIME) standard. When a message is parsed, it is broken into parts, each consisting of two sections. The first part is called the header section and it describes the format of the data and how it should be represented to the user. The second section is the data itself. A typical mail message without file attachments has one part, with the body of the message being the data. Messages with attachments have multiple parts, each with a header describing the type of data. The library can be then used to extract the data from a multipart message and save it to a file on the local system, delete the part from the message, or add additional parts to the message, such as attaching a file.

The library can also be used to create new multipart messages with alternative content, such a message with both plain text and styled HTML text. Once a message has been created, files can be attached to the message and the application can make any other changes that are needed. The library provides complete access to all headers and content in a multipart message, including the ability to create your own custom headers and make modifications to specific sections.

The first step that your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

MimeInitialize

Initialize the library for the current process. This must be the first function call that the application makes before calling the other MIME API functions.

MimeComposeMessage

Compose a new message using the specified header field values and content. Using this function, you can create a message with the From, To, Cc and Subject headers already defined, along with any text for the message. You can also optionally provide both plain and styled HTML text versions of the message and the function will automatically create a multipart message. The function returns a handle which can be used by the application to make further modifications, such as attaching files to the message.

MimeCreateMessage

Create a new, empty message and return a handle which can be used by the application to reference the message. In most cases, using the MimeComposeMessage function is preferred, however there may be some situations where the application needs a message handle when the contents of the message aren't known at the time. For example, parts of a message may be created dynamically based on the results of several database queries.

MimeDeleteMessage

Releases the memory allocated for the message and destroys the message handle. After this function returns, the handle is no longer valid. This function should be called when the message is no longer needed by the application.

MimeUninitialize

Release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Message Headers

Each message has one or more headers fields which provide information about the contents of the message. For example, the "From" header field specifies the email address of the person who sent the message. There are a fairly large number of header fields defined by the MIME standard, and applications can also create their own custom headers if they wish. The library gives the application complete access to the header fields in a message. Headers can be examined, modified, created or removed from the message as needed.

MimeGetMessageHeader

This function returns a pointer to a null terminated string which contains the value of the specified header field in the current message part. For languages like Visual Basic, it is recommended that you use the **MimeGetMessageHeaderEx** function instead.

MimeGetMessageHeaderEx

This function copies the value of a header field into a null terminated string buffer that you provide. This function also allows you to specify the message part in a multipart message. To return the value of the common header fields such as "From", "To" and "Subject", you should specify a message part of zero.

MimeGetFirstMessageHeader

This function returns the value of the first header defined in the current message part, copying it into the string buffer that you provide. This is used in conjunction with the MimeGetNextMessageHeader function to enumerate all of the headers that have been defined.

MimeGetNextMessageHeader

This function returns the value of the next header defined in the current message part. It should be called in a loop until it returns a value of zero (False) which indicates that the last message header has been returned.

MimeSetMessageHeader

Set a message header field to the specified value in the current message part. If the value is a null pointer or empty string, the message header will be deleted from the message.

MimeSetMessageHeaderEx

Set a message header field to the specified value. This version of the function allows you to also specify the message part, rather than just using the current message part. To return the value of the common header fields such as "From", "To" and "Subject", you should specify a message part of zero. If the value is a null pointer or empty string, the message header will be deleted from the message.

MimeDeleteMessageHeader

Delete the specified message header from the current message part.

Message Contents

The content or body of a message contains the text that is to be read or processed by the recipient. It may be a simple, plain text message or it may be more complex, such as a combination of plain and styled HTML text or the data for a file attachment. The library provides complete access to the contents of the message, enabling the application to modify, extract, replace or delete specific sections of the message.

MimeGetMessageText

Copy the text from the body of the current message part into a null terminated string buffer. The offset and length of the text being copied can be specified, which enables you to return just a portion of the message. For example, it would be possible to return just the first 1K byte of a text message.

MimeSetMessageText

Set or replaces the text in the body of the current message part. You can specify an offset in this function, enabling you to replace just portions of the message.

MimeAppendMessageText

Append text to the body of the current message part. Instead of replacing existing text, the new text will be added to the end of the message.

Multipart Messages

Most typical messages contain a single part, which consists of the message headers followed by the contents of the message. However, when files are attached to a message or alternative content types such as HTML are

used, a more complex multipart message is required. With a multipart message, the contents of the message are split into logical sections with each section containing a specific part of the message. For example, when a file is attached to a message, one part of the message contains the text to be read by the recipient and another part contains the data for the file.

The first of a multipart message is called part 0, and contains the main header block. This is what defines the headers that you are most familiar with, such as "From", "To" and "Subject". The body of this message part is typically a plain text message that indicates that this is a multipart message. This is done for the benefit of older mail clients that cannot parse MIME messages correctly. Next part, part 1, typically contains the actual body of the message that would be displayed by the mail client. Additional parts may contain file attachments and other information. In the case of a multipart message that contains both plain and styled HTML text versions of a message, part 1 is typically the plain text version of the message while part 2 contains the HTML version. The mail client can then make a decision based on its own configuration as to which version of the message it displays.

[MimeGetMessagePartCount](#)

Return the number of parts in the message. A simple message will contain just one part. This can be used to determine if the message is a MIME multipart message, with a value greater than one indicating that it is.

[MimeGetMessagePart](#)

Return the current message part. Each message has the concept of a "current message part", which is the default message part that the other functions will use. When a message is first created, the current message part is zero. The simplest way to think of message parts is as a zero-based index into an array into sections of the message.

[MimeSetMessagePart](#)

Change the current message part. Once the current message part has been set, it will remain as the current part until explicitly changed or until a new message part is created.

[MimeCreateMessagePart](#)

Create a new, empty message part. If the message was not originally a multipart message, it will be restructured into one. Otherwise, the new part is simply added to the end of the message. This function will cause the current message part to change to the new part that was just created.

[MimeCreateMessagePartEx](#)

Create a new message part using the specified character set and text. If the message was not originally a multipart message, it will be restructured into one. Otherwise, the new part is simply added to the end of the message. This function will cause the current message part to change to the new part that was just created.

[MimeDeleteMessagePart](#)

Delete the message part from the message. If the message part is in the middle of the message, it will cause the subsequent parts of the message to be reordered. You should not delete part zero to delete a message; use the **MimeDeleteMessage** function instead.

Importing Messages

The library can be used to import existing messages, either from memory or from a file. Once the message has been parsed, the application can examine or modify specific parts of the message. The following functions are provided to import the contents of a message:

[MimeImportMessage](#)

The simplest method of importing a message, this function reads the contents of the specified file and imports it into the current message. This function is typically called immediately after **MimeCreateMessage** to load a file into a new message context.

[MimeImportMessageEx](#)

This version of the function enables you to import the message from a file, the system clipboard, a pointer to a memory buffer or a global memory handle. This is typically used to import messages that were retrieved using the POP3 or IMAP protocols by passing a pointer to the buffer that contains the data returned by the server.

Exporting Messages

After a message has been created or modified, it can be exported to a file or to memory. Exporting the message to a memory buffer is particularly useful when using the library with another one of the SocketTools libraries. For example, the contents of a message can be exported to memory, and that memory address can be passed to the Simple Mail Transfer Protocol (SMTP) library for delivery to the recipient. The following functions are provided to export the contents of a message:

[MimeExportMessage](#)

This function exports the current message to a file. When using this function, only certain headers are exported and they may be reordered. To force all headers to be included in the message or to preserve the order of the headers, use the extended version of this function.

[MimeExportMessageEx](#)

This extended version of the function exports the message to a file, the system clipboard, a memory buffer or returns a handle to a global memory buffer that contains the message. There are additional options that enable you to control what headers are exported, and whether the order the headers were set should be preserved.

File Attachments

In addition to simple text messages, one or more files can be attached to a message. The process of attaching a file involves creating a multipart message, encoding the contents of the file and then including that encoded data in the message. The following functions are provided to manage files attached to the message, as well as attach files to an existing message:

[MimeAttachFile](#)

This function attaches the contents of the file to the message. The file will be attached using the specified encoding algorithm and will become the current message part. If the message is not a multipart message, it will be converted to one; if it already is a multipart message, the attachment will be added to the end of the message.

[MimeAttachData](#)

This function works in similar fashion to **MimeAttachFile**, except that instead of the contents of a file, the data in a memory buffer will be attached to the message. If the message is not a multipart message, it will be converted to one; if it already is a multipart message, the attachment will be added to the end of the message.

[MimeAttachImage](#)

This function attaches an inline image file to the message. It is similar to the **MimeAttachFile** function, except that the image is designed to be referenced as an embedded graphic in an HTML message. This function will automatically set the correct header values for an inline image attachment, and enables the developer to specify a content ID which is used in the HTML message.

[MimeGetAttachedFileName](#)

Return the name of a file attachment in the current message part. This function serves two purposes, to determine if the current message part contains a file attachment, and if so, what file name should be used when extracting that attachment.

[MimeExtractFile](#)

Extract the file attachment in the current message part, storing the contents in a file. The attachment

will automatically be decoded if necessary. This function also recognizes uuencoded attachments that are embedded directly in the body of the message, rather than using the standard MIME format.

Mail Addresses

The library has functions which are designed to make it easier to work with email addresses. Addresses are typically in the format of "user@domain.com" however additional information can be included with the address, such as the user's name or other comments that aren't part of the address itself. The library can parse these addresses for you, returning them in a format that is suitable for use with other protocols such as the SMTP library.

[MimeParseAddress](#)

Parse an email address that may include an address without a domain name or comments in the address, such as the user's name. For example, the From header field may return an address like "Joe Smith <joe@example.com>"; this function would parse the address and return "joe@example.com", the actual address for the user.

[MimeEnumMessageRecipients](#)

It is common for certain headers to contain multiple addresses separated by a comma. These addresses may also include comments such as the user's name. This function parses a string and returns a list of valid addresses. For example, the To header field may contain "Tom Jones <tom@example.com>, Jerry Lewis <jerry@example.com>"; this function would return "tom@example.com" and "jerry@example.com" as the two addresses listed.

Message Storage

The library has a collection of functions which makes it simple for an application to store a group of messages together in a single file, search for and retrieve specific message. The collection of messages is referred to as a "message store" and messages may either be stored in a plaintext format or in a compressed binary format.

[MimeOpenMessageStore](#)

This function is used to open an existing message store or create a new one. The function returns a handle which is used to access the messages in the storage file, and must be closed using the **MimeCloseMessageStore** function. The storage files may either be plaintext, or stored in a compressed format. It also supports opening storage files in the UNIX mbox format.

[MimeGetStoredMessageCount](#)

This function returns the number of messages that currently in the message store. Each message is referred to by an integer which is its index into the storage file. The first stored message has a value of 1, and increments with each additional message in the storage file.

[MimeFindStoredMessage](#)

An application can search the message store for messages that match any header value. Searches can be complete or partial, and may be case-sensitive or case-insensitive. For example, this function can be used to enumerate all of the messages in the storage file that were sent by a specific user or match a specific subject.

[MimeGetStoredMessage](#)

This function returns a handle to the message in the storage file, and can be used with any of the other functions in the Mail Message API. The application can also request its own private copy of the message, which it can modify independently of what is currently in the message store.

[MimeStoreMessage](#)

This function stores a new message, specified by its message handle, to the open message store. Note that the message store must be opened for write access, and this function will always append the message to the storage file. The new message index is returned to the caller.

MimeDeleteStoredMessage

This function flags a message for deletion from the message store. Once a message has been flagged for deletion, it may no longer be accessed by the application. When the storage file is closed, the contents of the deleted message will be removed from the file.

MimeReplaceStoredMessage

This function replaces an existing message in the storage file, overwriting it with the specified message. Unlike many of the other functions which do not permit the application to reference a deleted message, this function can be used to replace a previously deleted message.

MimeCloseMessageStore

The message store must be closed when the application has finished accessing it. The storage file is updated with any changes, all deleted messages are purged and the handle to the open file is closed. If the storage file is locked for exclusive access, this function will release that lock, allowing another process to open the file.

Network News Transfer Protocol

The Network News Transfer Protocol (NNTP) library enables applications to access a news server, list the available newsgroups, retrieve articles and post new articles. It is common for this library to be used in conjunction with the Mail Message library to construct the articles, since a news article uses the same general format as an email message.

The first step that your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

[NntpInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other NNTP API functions.

[NntpConnect](#)

Establish a connection to the NNTP server. This function will return a handle to a client session which is used in subsequent calls to the NNTP API.

[NntpAuthenticate](#)

Provide a user name and password to authenticate the client session. This should only be used if required by the server. Not all news servers require authentication, and some only require authentication when posting articles. If you attempt to perform a function that requires authentication, an error will be returned that indicates you should authenticate and then retry the operation.

[NntpDisconnect](#)

Disconnect from the NNTP server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

[NntpUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Newsgroups

News articles are posted in hierarchical groups, similar to how files are stored in folders. Each level in the newsgroup hierarchy is separated by a period, so newsgroup names look like microsoft.public.vc. This is Microsoft's newsgroup for articles about Visual C++ programming. Additional subgroups are used to further narrow the topic; for example, there's the microsoft.public.vc.3rdparty newsgroup for third party tools and components for Visual C++, and the microsoft.public.vc.atl newsgroup which discusses issues related to the Active Template Library. The NNTP API provides the following functions for accessing newsgroups on the server:

[NntpListGroup](#)

This function requests that the server return a list of all of the newsgroups that are available. If the function is successful, the application should call the [NntpGetFirstGroup](#) function to begin processing the group list.

[NntpListNewGroups](#)

This function is similar to the **NntpListGroup** function in that it requests the server to return a list of available newsgroups. However, the application can request that only groups which were created since a specific date should be returned. This allows the application to maintain a list of newsgroups on the local system, and then use this function to periodically update that list based on the date it was last modified.

[NntpGetFirstGroup](#)

This function is used in conjunction with the **NntpListGroup** or **NntpListNewGroups** functions to

enumerate the newsgroups that are available on the server. Information about the newsgroup is returned in a structure, including the name of the group, the first available article number and the last available article in the group.

[NntpGetNextGroup](#)

This function is used to return information about the next newsgroup in the list. It should be called in a loop until it returns zero (False).

[NntpSelectGroup](#)

This function is used to select a newsgroup as the current group. Once selected, the application has access to the articles in that newsgroup.

[NntpGetGroupName](#)

Return the name of the currently selected newsgroup.

[NntpGetGroupTitle](#)

Return a description of the currently selected newsgroup. Note that not all newsgroups have associated descriptions, and some servers may not support the extended command which is used to retrieve the description.

News Articles

News articles are the messages posted to one or more newsgroups. Articles are referenced by their article number, which is a value assigned by the news server. These articles have a structure that is the same as an email message, with some slightly different headers. Because of this, you can use the Mail Message API to parse articles that you retrieve, as well as create new articles to post to the server. The following functions are used to access and create news articles:

[NntpListArticles](#)

This function requests that the server return a list of articles that are available in the current newsgroup. The application can request that all articles be returned, or only those articles which fall into a certain range of article numbers.

[NntpGetFirstArticle](#)

This is the first function that should be called after the **NntpListArticles** function. It will return information about the first article in the list. Article information is returned in a structure which includes information such as the article ID, size, subject, author and date that the article was posted.

[NntpGetNextArticle](#)

This function returns the information about the next article in the list. It should be called in a loop until the function returns zero (False).

[NntpGetArticleRange](#)

Return the range of articles that are available in the currently selected newsgroup. These are the first and last valid article numbers that can be used to retrieve an article from the server. It is important to keep in mind that there is no requirement that articles be stored contiguously with no gaps in between them. For example, say the first available article number in the newsgroup is 101 and the last available article number is 120; it does not necessarily mean that there are 20 available articles. Articles 112 and 118 may have been removed, in which case your application would get an error when trying to access them. The inability to access an article within the article range should not be considered a fatal error; the program should simply move on to the next message.

[NntpGetArticle](#)

Retrieve an article from the server, storing the contents in memory. This can be used to process the contents of an article without the overhead of storing it in a file on the local system.

[NntpStoreArticle](#)

Retrieve an article from the server and store it in a file on the local system.

[NntpPostArticle](#)

This function posts an article to one or more newsgroups on the server. A newsgroup article is similar to an email message, and the MIME API may be used to create the article headers and body. One important difference is that the message must contain a header named "Newsgroups" with the value set to the newsgroup or newsgroups that the article should be posted to; multiple newsgroups should be separated by commas. If this header is not defined, the posting will be rejected by the server and the function will return an error. You should also be aware that some servers limit the number of newsgroups that a message can be posted to. When an article is posted to more than one newsgroup at a time, this is called cross-posting. Current convention says that an article should not be cross-posted to more than five newsgroups at a time. Also keep in mind that multi-posting (posting the same article to different newsgroups separately) is generally discouraged and should never be done on USENET.

Attaching Files

It is possible to attach files to newsgroup articles; however it should only be done if it is considered appropriate for the group. Many newsgroups have their own acceptable use policies which determine whether or not file attachments, particularly large binary files, are acceptable. If the newsgroup accepts attachments, you can use one of several methods for posting files. It is recommended that you use the [File Encoding](#) API to handle the actual encoding of the data.

Uuencode

A uuencoded file attachment is included directly in the body of the message. Because the MIME API creates a multipart message even when uuencoding is specified, the File Encoding API should be used to encode the data and then it should be included in the main body of the message.

Base64

A Base64 file attachment has the same structure as what is used by email messages. This requires that a multipart message be created, with the encoded data attached as a part of the message. You can use the MIME API to create this kind of message. Note that not all third-party newsreaders correctly handle multipart messages.

yEnc

A popular encoding method used on USENET is called yEnc. Similar to uuencoded attachments, the file data is part of the body of the message. The File Encoding API should be used to encode the data and then it should be included in the main body of the message.

News Feed Library

Really Simple Syndication (RSS) is a collection of standardized formats that are used to publish information about content that is frequently changed. A news feed is published in XML format, which contains one or more items that includes summary text, hyperlinks to source content and additional metadata that is used to describe the item. News feeds can be used for a variety of purposes, including providing updates for weblogs, news headlines, video and audio content. RSS can also be used for other purposes, such as a software updates, where new updates are listed as items in the feed.

News feeds can be accessed remotely from a web server, or locally as an XML formatted text file. The source of the feed is determined by the URI scheme that is specified. If the http or https scheme is specified, then the feed is retrieved from a web server. If the file scheme is used, the feed is considered to be local and is accessed from the disk or local network. The News Feed library provides an API that enables you to open a feed by URL and iterate through each of the items in the feed or search for a specific feed item. The API also provides a function that can be used to parse a string that contains XML data in RSS format, where the feed may have been retrieved from other sources such as a database.

The first step your application must take is to initialize the library, which will load the required system libraries and initialize the internal data structures that are used. You must call the initialization function before attempting to call any other function in the library.

[RssInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other SMS API functions.

[RssUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

News Channels

A news feed consists of a channel that contains each of the news feed items. The news channel is represented in the library by an **HCHANNEL** handle. This handle is used with the other functions to reference the specific news feed channel. Information about the news feed, such as the title of the channel and the date it was last modified, is returned in an [RSSCHANNEL](#) structure.

[RssOpenFeed](#)

Open the channel by specifying a URL to the resource that contains the news. The URL can identify a remote feed that is downloaded using the HTTP or HTTPS protocols, or it can be a file on the local system or network.

[RssParseFeed](#)

Parse a string buffer that contains a news feed. This function is similar to the **RssOpenFeed** function, however it is used to parse a string that contains the news feed. This function would typically be used when the feed content is obtained from a different source, such as a database or by using a different protocol. For example, the news feed could be downloaded using the FTP API and then passed to this function.

[RssCloseFeed](#)

This function closes the handle that was allocated by a previous call to the **RssOpenFeed** or **RssParseFeed** function. When the information in a news feed is no longer needed, this function must be called to release the resources allocated to process the feed. After this function is called, the handle is no longer valid.

[RssValidateFeed](#)

This function is used to validate the contents of a news feed, ensuring that it is structured correctly.

The function will return information about the feed, including the number of news items in the feed and the date that it was last modified. The news feed can be specified either as a URL to a remote resource or as a file on the local system or network.

[RssStoreFeed](#)

This function is used to store a news feed as a file on the local system. This is typically used to cache the contents of a news feed or to track the changes made to the feed over time. It is recommended that the application periodically check the publication date of the feed to ensure that they have current version.

News Items

News feed items are identified by a numeric value called the item ID. This is used with other functions to return information about a specific news item. The first item in a news feed has an ID of one and it increments for each additional item in the feed, although it is recommended that applications treat this as an opaque value. Functions are provided which will return the number of items in a news feed, information about each item and enable you to easily enumerate each of the items in the feed. Information about a particular news item is returned in an **RSSCHANNELITEM** structure.

[RssGetItemCount](#)

This function will return the number of news items in the feed.

[RssGetFirstItem](#) / [RssGetNextItem](#)

These functions are used to enumerate the items in the news feed. Details about each news item is returned in an **RSSCHANNELITEM** structure which contains information such as the title, description and author of the news item.

[RssGetItem](#)

This function is used to return information about a specific news item based on the item ID. When the function returns, it will populate an **RSSCHANNELITEM** structure. Although this function can be used to effectively enumerate all of the news feed items by starting with an item ID value of one, it's recommended that you use the **RssGetFirstItem** and **RssGetNextItem** functions instead. Your application should never make an assumption about the actual value of the item ID because there's no guarantee that future versions of the library will assign item IDs sequentially. Best practices dictate that the **RssGetItem** function should only be called using an item ID that was previously obtained by a call to either the **RssGetFirstItem**, **RssGetNextItem** or **RssFindItem** functions.

[RssFindItem](#)

This function is used to search the feed channel for a specific item, based either on its GUID, title, link or publication date. When searching for a specific item, only searches by GUID are guaranteed to return a unique news item. However, since not all news feeds may provide GUIDs for their news items, additional search criteria can be used when necessary. If the function is successful, it will populate an **RSSCHANNELITEM** structure with information about the news feed item.

[RssGetItemText](#)

This function is used to return a copy of the news item description based on the item ID. Internally, this function calls **RssGetItem** and then copies the item description to the string buffer that is provided by the caller. Note that it is the responsibility of the application to display the text in the appropriate format. Most news feeds will either use plain text or HTML formatted text for the item description.

Post Office Protocol

The Post Office Protocol (POP3) library enables an application to retrieve a user's mail messages and store them on the local system. The POP3 API provides support for all of the standard functionality such as listing and downloading messages, as well as extended features such as the ability to retrieve only the headers for a message or just specific header values. The library also has functions for changing the user's password and sending messages if they are supported by the server.

The first step your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

PopInitialize

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call the application makes before calling the other POP3 API functions.

PopConnect

Establish a connection to the POP3 server. This function will return a handle to a client session which is used in subsequent calls to the POP3 API.

PopLogin

Authenticate yourself to the server using a username and password. This function should be called immediately after the connection has been established to the server. You can specify either the standard authentication method, or the APOP authentication method if required by the server.

PopDisconnect

Disconnect from the POP3 server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

PopUninitialize

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Managing Messages

There are functions in the POP3 library for managing messages which enables the application to list, delete and retrieve messages stored on the server. Messages are identified by a number, starting with one for the first message in the mailbox. The most typical operation for a POP3 client is to retrieve each message, store it on the local system and then delete the message from the server. Any processing that is done on the message would then be done on the local copy.

PopGetMessageCount

Return the number of messages available for retrieval. There are two values the application should use. One is the number of currently available messages and the other is the last valid message number. As messages are deleted from the server, the total number of available messages will decrease; however, the last available message number will remain constant.

PopGetMessageCountEx

An extended version of the **PopGetMessageCount** function, this function will return the number of available messages, along with the last available message number and the total size of all messages in the mailbox.

PopGetMessage

Retrieve a message from the server, storing the contents in memory. This can be used to process the contents of a message without the overhead of storing it in a file on the local system.

PopStoreMessage

This function downloads a complete message and stores it as a text file on the local system.

PopDeleteMessage

Mark the message for deletion. When the connection with the server is closed, the message will be removed from the user's inbox. An important difference between the POP3 and IMAP protocols is that when a message is marked as deleted on a POP3 server, that message can no longer be accessed. An attempt to retrieve a message after it has been marked for deletion will result in an error. The only way to undelete a message once it has been deleted is to terminate the connection with the server by calling the **PopReset** function instead of calling **PopDisconnect**.

PopGetMessageSize

This function returns the size of the message in bytes. One thing to be aware of when using this function is that some servers will only return approximate message sizes. In addition, because of the difference between the end-of-line characters on UNIX and Windows systems, the size reported by the server may not be the actual size of the message when stored on the local system. Therefore, the application should not depend on this value as an absolute. For example, it should not use this value to determine the maximum number of bytes to read from the server; instead, it should read until the server indicates that the end of the message has been reached.

Message Headers

The POP3 API also includes functions which enable the application to access just the headers for a message. This can be useful if the program doesn't want to incur the overhead of downloading the entire message contents. The following functions can be used to examine the headers in a message:

PopGetMessageHeaders

This function returns the complete set of headers for the specified message. If your program has to process multiple header fields, this is the most efficient method to use. It is possible to retrieve specific header values, however not all servers support that option and it is somewhat slower because it involves sending individual commands to request each value.

PopGetHeaderValue

This function returns the value for a specific header field in a message. This function does not require that you parse the message headers; however it does incur additional overhead. It is also important to note that not all servers support the command that is used to request the header value. If this function fails with the error that the feature is not supported, you should use the **PopGetMessageHeaders** function instead.

PopGetMessageId

This function returns the value of the Message-ID header in the specified message. This is a unique string that is used to identify the message. Note that it is not the same as the UID value returned by the POP3 server.

PopGetMessageUid

This function returns the unique ID (UID) that the server has associated with the message. The UID can be used by an application to track whether or not it has previously viewed the message. Unlike the message number, which can change between client sessions, the message UID is guaranteed to be the same value across sessions until the message is deleted.

PopGetMessageSender

This function returns the email address of the person who sent the message. This function requires that the server support extended POP3 commands. If the server does not support the command used to retrieve the sender, it will return a value of zero. Applications should not depend on this function returning a valid address. Typically it is used for informational purposes, such as displaying the sender to the user as a message is being retrieved.

Remote Command Protocol

The Remote Command protocol enables an application to execute commands on a server, with the output of the command returned to the client. The SocketTools library actually implements three related protocols: rexec, rshell and rlogin. The choice of protocols is determined by the port that is selected when a connection is established.

Rexec

The rexec protocol enables a client application to execute a command on a server. Output from the command is returned to the client and the connection is closed when the command terminates. The client connects on port 512 and must provide a user name and password to authenticate the session.

Rshell

The rshell protocol is similar to rexec in that it enables a client to execute a command on a server. Output from the command is returned to the client and the connection is closed when the command terminates. The client connects on port 514 and must provide a user name. The primary difference between the rexec and rshell protocols is that rshell does not require a password. Instead, it uses what is called "host equivalence" to determine if the client is permitted to execute commands as that user. On a UNIX based operating system, host equivalence is controlled by the /etc/hosts.equiv and the .rhosts file in the user's home directory. These files list the host names and user names which are permitted to execute commands using the rshell protocol. Consult your operating system manual pages for more information about how to configure host equivalence.

Rlogin

The rlogin protocol is similar to Telnet in that it provides an interactive terminal session. The connection is closed when the user logs out or the shell process on the server is terminated. The client connects on port 513 and must provide a user name and terminal type. If there is an entry in the host equivalence tables for the user and local host, then the client will be automatically logged in and provided with a shell prompt. If there is no host equivalence, the client will be prompted for a password. The terminal emulation library can be used to provide ANSI or DEC VT-220 emulation services if needed.

An important consideration when deciding whether to use rexec, rshell or rlogin is how the server is configured and the type of command being executed. If there is no entry for the local host in the server's host equivalence tables, then the rexec command should be used instead of rshell.

When using rexec or rshell, it is important to keep in mind that although the command is executed with the privileges of the specified user, that user is not actually logged in. The user's login script is not executed and the program will not inherit the user's normal environment as it would during an interactive session. If you are connecting to a UNIX system, you should not attempt to execute programs which try to put standard input into raw mode; an example of this would be the vi editor. If you are connecting to a Windows system, you should not execute a program which uses a graphical interface. Only programs which read standard input and write to standard output are suitable for use with rexec or rshell.

The first step that your application must take is to initialize the library and then establish a connection. The following functions are available for use by your application:

RshInitialize

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other Remote Command API functions.

RshExecute

Execute the specified command on the server. The rshell or rexec protocol is selected based on the port number that is specified. Output from the command will be returned to the client to be read. When the command terminates, the connection to the server will be closed.

[RshLogin](#)

Establish an interactive login session which is similar to how the Telnet protocol works. If there is no host equivalence with the local host, you will be prompted for a password. Output from the session will be returned to the client, and when the client logs out the connection will be closed.

[RshRead](#)

Read the output generated by the command. Your application would typically call this function in a loop until all of the data has been read or an error occurs.

[RshSearch](#)

Search for a specific sequence of characters in the output returned by the server. The function returns when the sequence is encountered or when a timeout occurs. The data captured up to the point where the character sequence was matched is returned to the caller for processing.

[RshDisconnect](#)

Disconnect from the server and release the memory allocated for that client session. After this function is called, the client handle is no longer valid.

[RshUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Secure Shell Protocol

The Secure Shell (SSH) protocol enables an application to establish a secure, interactive terminal session with a server, or execute commands remotely on the server, with the output of the command returned to the client. The SocketTools library supports both version 1.0 and 2.0 of the protocol.

The first step that your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

[SshInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call the application makes before calling the other SSH API functions.

[SshConnect](#)

Establish a connection to the server. This function will return a handle to a client session which is used in subsequent calls to the SSH API.

[SshDisconnect](#)

Disconnect from the server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

[SshUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Connection Options

The SSH protocol has a number of advanced options which can be specified when establishing a connection. To provide additional information to the connection function, the [SSH_OPTIONDATA](#) structure is used. The three most commonly used options specify if the connection will be used for an interactive terminal session or to execute a command on the server, and if a proxy server should be used when connecting to the server:

SSH_OPTION_TERMINAL

This option specifies the client session will use terminal emulation and the [SSH_OPTIONDATA](#) structure specifies the characteristics of the virtual terminal. This enables the caller to specify the dimensions of the virtual display (in columns and rows) and the type of terminal that will be emulated. If this option is omitted, the session will default to a virtual display that is 80 columns, 25 rows.

SSH_OPTION_COMMAND

This option specifies the client session will be used to issue a command that is executed on the server, and the output will be returned to the caller. If this option is specified, the session will not be interactive and no pseudo-terminal is created for the client. The ***szCommandLine*** member of the [SSH_OPTIONDATA](#) structure specifies the command string that will be sent to the server.

SSH_OPTION_PROXYSERVER

This option specifies the client should establish a connection through a proxy server. The two protocols that are supported are [SSH_PROXY_HTTP](#) and [SSH_PROXY_TELNET](#), which specifies the protocol that the proxy connection is created through. The proxy-related members of the [SSH_OPTIONDATA](#) structure should be set to the appropriate values.

Input and Output

Once your application has connected to the server, any output generated by a program on the server will be sent as data for you to read. Any input to the program is sent by your application and received and processed by the server. The following functions are used:

[SshPeek](#)

Reads any data that has been sent by the server and copies it to the buffer provided by the caller, but

it does not remove the data from the internal receive buffer. This function can be used to examine the contents of the receive buffer and make decisions about how to process the data.

[SshRead](#)

Reads any data that has been sent by the server and copies it to a byte array buffer provided by your application. If the server closes the connection, the function will return a value of zero and the client can disconnect from the server at that point.

[SshReadLine](#)

Reads a line of text from the server, and returns it as a null terminated string. This function is useful for reading output from the server one line at a time. The function recognizes both UNIX and Windows end-of-line conventions, and will cause the application to block until a complete line of text has been read.

[SshWrite](#)

Send data to the server which will be received as input to the program. Your application provides the function with a byte array buffer that contains the data, and an integer value that specifies the number of bytes in the buffer.

[SshWriteLine](#)

Send data to the server as a line of text, terminated with a carriage-return and newline character. Note that your application should not specify the end-of-line characters, they are automatically sent to the server. This function will cause the application to block until the complete line of text has been written.

Command Processing

The SSH protocol can be used to connect to a server, log in and execute one or more commands, process the output from those commands and display it to an end-user using a graphical interface. The user never needs to see or interact with the actual terminal session. The SSH API provides functions which can simplify this kind of application, reducing the amount of code needed to process the data stream returned by the server.

[SshExecute](#)

This function executes a command on a server and copies the output to a user-specified buffer, with the exit code for the remote program as the function's return value. This is a convenience function that enables you to execute a remote command in a single call, without having to write the code to establish the connection and read the output.

[SshGetExitCode](#)

This function returns the exit code for the program that was executing on the server. It should be called after all of the data has been read and the server has closed the connection, which is indicated by the **SshRead** function returning a value of zero.

[SshSearch](#)

This function is used to search for a specific character or sequence of characters in the data stream returned by the server. The library will accumulate all of the data received up to the point where the character sequence is encountered. This can be used to capture all of the output from a command, or search for specific results returned by the command as it executes on the server.

Simple Mail Transfer Protocol

The Simple Mail Transfer Protocol (SMTP) enables applications to deliver email messages to one or more recipients. The library provides an API for addressing and delivering messages, and extended features such as user authentication and delivery status notification. This library is typically used in conjunction with the Mail Message library to create the messages, and the Domain Name Service library to determine what servers are responsible for accepting mail for a specific user.

Mail Exchanges

When a message is delivered to a user, the application must determine what mail server is responsible for accepting messages for that user. This can be accomplished using the Domain Name Services (DNS) protocol, a protocol that is most commonly used to resolve host names such as `www.microsoft.com` into Internet addresses. This is typically accomplished by sending a request to a nameserver, a computer system that provides domain name services. In addition to resolving host names, nameservers can also provide information about those servers which are responsible for accepting mail for a given domain. There can be multiple servers which process mail for a domain with each server assigned a priority as part of their mail exchange (MX) record. If there is no mail exchange record for a domain, then the domain name itself is used.

To deliver a message directly to the recipient, you must examine the recipient address and request the list of mail exchanges for that user's domain. Using the DNS API, this is done by calling the

DnsEnumMailExchanges function. If the recipient address is `joe@example.com`, you would want to enumerate the mail exchanges for the `example.com` domain. This will give you the name of the servers that will accept mail for users in that domain. For example, the function may return the host name `mail.example.com` as the name of the server which will accept mail for users in the `example.com` domain. Note that it is possible that one or more of the mail exchanges for a domain may not be in the recipient domain itself. In other words, it is possible that `smtp.othercorp.net` could be returned as a mail exchange for `example.com`. This is frequently the case when another organization is forwarding mail for that domain.

Therefore, there are three general steps that you must take when delivering mail directly to the recipient:

1. Parse the address of each recipient in the message. If you are using the MIME API, the **MimeEnumMessageRecipients** function can be helpful in extracting all of the recipient addresses. Everything after the atsign (@) in the address is the domain portion of that address.
2. Perform an MX record lookup using the DNS API function **DnsEnumMailExchanges** and specifying the recipient's domain. The function will return the name of the servers responsible for accepting mail for that user. If there are more than one server, they will be returned in order of their relative priority, with the highest priority server being returned first. This means that you should attempt to connect to those servers in the order that they are returned by the function.
3. Attempt to connect to the first server returned by the **DnsEnumMailExchanges** function. The connection should be on the default port, and you should not attempt to use any authentication. If the server accepts the connection, then use the **SmtpSendMessage** function to deliver the message. If the connection is rejected or the message is not accepted, attempt to connect to the next mail exchange server until all servers have been tried.
4. If no mail exchange servers were returned by **DnsEnumMailExchanges**, or you could not connect to any of them, attempt to connect to the domain specified in the address using the default port. If the connection succeeds, then deliver the message. If you cannot connect or the message is not accepted, then report to the user that the message could not be delivered.

One last important consideration is that many Internet Service Providers now block outbound connections on port 25 to any mail servers other than their own. If you are unable to establish any connections, either with the

error that the connection was refused or it consistently times out, contact your ISP to determine if port 25 is being blocked as an anti-spam measure. If this is the case, it will be required that you relay all messages through their mail servers or use an alternate port number.

Relay Servers

In some situations it may not be possible to send mail directly to the server that accepts mail for a given domain. The two most common situations are corporate networks which have centralized servers that are responsible for delivering and forwarding messages, or an Internet Service Provider (ISP) which specifically blocks access to all mail servers other than their own. This is usually done as either a security measure or as a means to inhibit users from sending unsolicited commercial email messages. If the standard SMTP port is being blocked, then any connection attempts will either fail immediately with an error that the server is unreachable, or the connections will simply time-out. In either case, a relay server must be specified in order to send email messages.

A relay server is a system which will accept messages addressed to users who may be in a different domain, and will relay those messages to the appropriate server that does accept mail for the domain. Using a relay server is generally easier than sending messages directly to the recipient. In order to send a message through a relay, you need to perform the following steps:

1. Connect to the relay server as you would normally.
2. Authenticate the client to the server. This may or may not be required, depending on how the server is configured. Some servers may be configured to only require authentication if you are connecting from an IP address that is not recognized as part of that system's network, for example, if you are connecting using a different Internet Service Provider. Others may always require authentication. Check with the server administrator if necessary to determine if and when authentication is required.
3. Use the **SmtpSendMessage** function to deliver the message to the recipients through the relay server. If there are multiple recipients, you can use the MIME API to enumerate the recipient addresses and then pass them to the **SmtpSendMessage** function.

It is important to note that using a mail server as a relay without the permission of the organization or individual who owns that server may violate Acceptable Use Policies and/or Terms of Service agreements with your service provider. Systems which relay messages from anyone, regardless of whether the message is coming from a recognized domain, are called open relays. Because open relays are often used to send unsolicited email, many administrators block mail that comes from one. It is recommended that users check with their network administrators or Internet service providers to determine if access to external mail servers is restricted and what is the acceptable use policy for relaying messages through their mail servers.

The first step your application must take is to initialize the library, then establish a connection to the server and authenticate the client if necessary. The following functions are available for use by your application:

[SmtpInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other SMTP API functions.

[SmtpConnect](#)

Establish a connection to the SMTP server. This function will return a handle to a client session which is used in subsequent calls to the SMTP API.

[SmtpAuthenticate](#)

Authenticate the client session to the server using a username and password. This function should be called immediately after the connection has been established to the server. This is typically required if you are attempting to use the mail server as a relay, asking it to forward the message on to the server that actually accepts email for the recipient. Many Internet Service Providers (ISPs) require that users

authenticate prior to sending mail through their servers. You may need to contact the server administrator to determine if authentication is required.

[SmtpDisconnect](#)

Disconnect from the SMTP server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

[SmtpUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Message Delivery

There are two general methods that can be used to deliver messages through the mail server. In most cases, it can be done with a single function call. However, there are some circumstances where it would be more appropriate to perform the transaction in stages. The SMTP API supports both methods.

[SmtpSendMessage](#)

This is the simplest method for sending an email message through the server. You provide the sender and recipient addresses, along with the message contents and the function will submit the message to the server for delivery.

[SmtpCreateMessage](#)

This function begins a transaction in which a message is dynamically composed, addressed and delivered in stages. You provide the sender address and message size to this function, and after it returns you begin the next stage, which is addressing the message.

[SmtpAddRecipient](#)

This function adds a recipient address to the recipient list for the message. This should be called once for each recipient, as well as for any recipients who are to receive "blind copies" of the message. A blind copy is when the message is sent to a recipient, but that recipient's address is not listed in any of the headers of the message; the other recipients will be unaware that the message was delivered to him. Most servers have a limit of approximately 100 recipients per message. It is possible that this function will return an error for a specific recipient address; the address may be malformed or it may not be acceptable for some other reason. This does not mean that the message will be rejected in its entirety, only that the specified recipient is not acceptable.

[SmtpAppendMessage](#)

This function should be called after all of the recipients have been added. It is used to send the contents of the message to the server. It is also possible to use the lower level **SmtpWrite** function to send data directly to the server, however **SmtpAppendMessage** is generally easier to use and can write data from memory, the system clipboard or from a file on disk.

[SmtpCloseMessage](#)

This function is called after the entire message has been sent to the server. This terminates the transaction and the message is submitted for delivery. Note that it is possible for the server to accept the message up to this point and then reject it at this final step due to some restriction, such as the message being too large.

SocketWrench

The SocketWrench library provides an interface to the Windows Sockets API. It was designed to be simpler to use, and to provide functions which eliminate much of the redundant coding common to Windows Sockets programming. Developers who are working in languages other than C or C++ will find SocketWrench to be particularly useful because it does not use many of the complex structures that the Windows Sockets API uses. SocketWrench also supports creating client and server applications which use TLS security protocol without any dependencies on third-party security libraries.

The first step your application must take is to initialize the library. After the library has been initialized, the application can either take on the role of a client and establish a connection to a server, or become a server and listen for incoming connections from other clients.

InetInitialize

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call the application makes before calling the other SocketWrench API functions.

InetConnect

Establish a connection with a server. This function will return a handle to the application which can be used to send and receive data. When an application calls this function, it will be acting as a client. For an asynchronous session, use the **InetAsyncConnect** function.

InetListen

Begin listening for incoming client connections. This function will return a handle which should be passed to the **InetAccept** function to accept any clients which establish a connection. When an application calls this function, it will be acting as a server. For an asynchronous session, use the **InetAsyncListen** function.

InetAccept

Accept a connection from a client. This function should only be called if the application has previously called **InetListen**. If there is no client waiting to connect at the time this function is called, it will block until a client connects or the timeout period is reached. For an asynchronous session, use the **InetAsyncAccept** function.

InetUninitialize

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Input and Output

When a TCP connection is established, data is sent and received as a stream of bytes. The following functions can be used to send and receive data over the socket:

InetRead

Read data from the socket and copy it to the memory buffer provided by the caller. If the server closes the connection, this function will return zero after all the data has been read. If the function is successful, it will return the actual number of bytes written.

InetIsReadable

This function is used to determine if there is data available to be read from the socket.

InetWrite

Write data to the socket. If the function succeeds, the return value is the number of bytes actually written.

InetIsWritable

This function is used to determine if data can be written to the socket. In most cases this will return a

non-zero value (True), unless the internal socket buffers are full.

Server Interface

The library provides a collection of functions which can be used to easily create a scalable, event-driven multithreaded server application. The server runs on a separate thread in the background, automatically managing the individual client sessions as servers connect and disconnect from the server. The application is notified of events through a callback mechanism, where it can respond to notifications such as a client establishing a connection with the server, or the client sending data to the server. Functions such as **InetRead** and **InetWrite** are used to exchange data with the clients. Because each client session is managed in its own thread, applications can perform calculations, access database resources and so on without worrying about interfering with other client sessions or the application's main UI thread.

[InetServerStart](#)

This function starts the server, creating the background thread and listening for incoming client connections on the specified port number. A socket handle is returned to the caller which is used to query the status of the server and perform other functions such as suspending and restarting the server.

[InetEnumServerClients](#)

This function enables the server application to determine the number of active client sessions, and obtain socket handles for each client that is connected to the server.

[InetServerBroadcast](#)

Broadcasts data to each of the clients that are connected to the server. This can be useful when the application needs to send the same data to each active client session, such as broadcasting a shutdown message when the server is about to be terminated.

[InetServerThrottle](#)

This function is used to control the maximum number of clients that may connect to the server, the maximum number of clients that can connect from a single IP address and the rate at which the server will accept client connections. By default, there are no limits on the number of active client sessions and connections are accepted immediately. This function can be useful in preventing denial-of-service attacks where the attacker attempts to flood the server with connection attempts.

[InetServerSuspend](#)

This function instructs the server to temporarily suspend accepting new client connections. Existing connections are unaffected, and any incoming client connections are queued until the server is resumed. It is not recommended that you leave a server in a suspended state for an extended period of time. Once the connection backlog queue has filled, any subsequent client connections will be automatically rejected.

[InetServerResume](#)

This function instructs the server to resume accepting client connections after it was suspended. Any pending client connections are accepted after the server has resumed normal operation.

[InetServerLock](#)

This function locks the server so that only the current thread may interact with the server and the client sessions. This will cause all other client threads to go to sleep, waiting for the server to be unlocked. This should only be used when the server application needs to ensure that no other client threads are performing a network operation. For general purpose synchronization, it is recommended that the application create a critical section rather than lock the entire server. If the server is left in a locked state for an extended period of time, it will cause the server to become non-responsive. If the application has started multiple servers, only one server can be locked at any one time.

[InetServerUnlock](#)

This function unlocks a server that has been previously locked. The threads which manage the client sessions will awaken and resume normal execution.

[InetServerRestart](#)

This function will terminate all active client connections, close the listening socket and re-create a new listening socket bound to the same address and port number. The function will return a socket handle for the new listening socket that should replace the original socket that was allocated using the **InetServerStart** function.

[InetServerStop](#)

This function will terminate all active client connections, close the listening socket and terminate the background thread that manages the server. Any incoming client connections will be refused, and all resources allocated for the server will be released.

Address Conversion

Internet Protocol (IP) addresses can be represented in one of two ways, either as unsigned 32-bit integer value or as string where each byte of the address is written as an integer value and separated by periods. For example, the local loopback IP address can either be specified as the string "127.0.0.1" or as the integer value 16777343. In most cases, using the string form of the address is easier; however, some functions require that the numeric value be used. The following functions are provided to enable you to convert between the two formats.

[InetGetAddress](#)

Convert an IP address string in dotted notation into a 32-bit integer value.

[InetFormatAddress](#)

Convert a numeric IP address into a string in dotted notation, copying the result into a buffer that you provide to the function.

Host Tables

When resolving a host name or IP address, the library will first search the local system's host table, a file that is used to map host names to addresses. On Windows 95/98 and Windows Me, if the file exists it is usually found in C:\Windows\hosts. On Windows NT and later versions, it is found in C:\Windows\system32\drivers\etc\hosts. Note that the file does not have an extension.

[InetGetDefaultHostFile](#)

Return the full path of the file that contains the default host table for the local system. This can be useful if you wish to temporarily switch between the default host file and another host file specific to your application.

[InetGetHostFile](#)

Return the full path of the host table that is currently being used by the library. Initially this is the same as the default host table for the local system.

[InetSetHostFile](#)

Specify a new host table which the library should use to resolve host names and IP addresses. This can be used by an application to provide its own local cache of host names and addresses in order to speed up the process of host name resolution.

Host Name Resolution

The library can be used to resolve host names into IP addresses, as well as perform reverse DNS lookups converting IP addresses into the host names that are assigned to them. The library will search the local system's host table first, and then perform a nameserver query if required.

[InetGetHostAddress](#)

Resolve a host name into an IP address, returned as a string in dotted notation. The library first checks

the system's local host table, and if the name is not found there, it will perform a nameserver query for the A (address) record for that host.

[InetGetHostName](#)

Resolve an IP address into a host name. The address is passed as a string in dotted notation, and the fully qualified host name is returned in a string buffer you provide to the function. The library first checks the system's local host table, and if the address is not found there, it will perform a nameserver query for the PTR (pointer) record for that address.

Local Host Information

Several functions are provided to return information about the local host, including its fully qualified domain name, local IP address and the physical MAC address of the primary network adapter.

[InetGetLocalName](#)

Return the fully qualified domain name of the local host, if it has been configured. If the system has not been configured with a domain name, then the machine name is returned instead.

[InetGetLocalAddress](#)

Return the IP address of the local host. If a valid socket handle is provided, then the IP address of the network adapter that was used to establish the connection will be returned. This can be particularly useful for multihomed systems that have more than one adapter and the application needs to know which adapter is being used for the connection.

[InetGetAdapterAddress](#)

Return the IP or MAC address assigned to a network adapter on the local system.

[InetEnumNetworkAddresses](#)

Enumerate the network addresses that are configured for the local host. If the system is multihomed, then the IP address for each network adapter will be returned.

Telnet Protocol

The Telnet Protocol library enables an application to connect to a Telnet server, which provides an interactive terminal session similar to how character based consoles and terminals work. The user can login, enter commands and interact with applications programmatically or in conjunction with the terminal emulation library.

The first step that your application must take is to initialize the library, then establish a connection to the server and authenticate the client. The following functions are available for use by your application:

TelnetInitialize

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call the application makes before calling the other Telnet API functions.

TelnetConnect

Establish a connection to the Telnet server. This function will return a handle to a client session which is used in subsequent calls to the Telnet API.

TelnetDisconnect

Disconnect from the Telnet server and release any resources that have been allocated for the client session. After this function is called, the client handle is no longer valid.

TelnetUninitialize

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call that the application should make prior to terminating.

Input and Output

Once connected to the Telnet server, any output generated by a program on the server will be sent as data for the client to read. Any input to the program is sent by the client and received and processed by the server. The following functions are used:

TelnetRead

Reads any output that has been generated by the program executing on the server. When the client first connects, the server typically executes a login program that requests the users authenticate themselves by entering a user name and password. Once the user has logged in, they are usually given a command line prompt where they can enter commands to be executed on the server. If the server closes the connection, the **TelnetRead** function will indicate that with an error result and the client can disconnect from the server at that point.

TelnetWrite

Send data to the Telnet server which will be received as input to the program. If the local echo option is enabled, then the client is also responsible for writing the input data to the display device, if there is one. If local echo is not enabled, the server will automatically echo back any characters written as data to be read by the client.

Telnet Modes

Telnet supports several modes of operation and the option negotiation phase, which occurs when a connection is established, is handled automatically by the library. There are two key modes which affect how the client session works:

TELNET_MODE_LOCALECHO

If this mode is enabled, it is the responsibility of the client to echo any data that it is sending to the server. For example, if the character "A" is sent to the server, the application must also send the character "A" to whatever interface the user is interacting with, such as a terminal emulation window. The default mode is for this option to be disabled, which means that the server will echo back any

data that is sent to it.

TELNET_MODE_BINARY

If this mode is enabled, the data between the client and server is not buffered and the high bit is not removed from any characters. If the application is executing a program which uses text mode windowing features (i.e.: it draws boxes on the display) then this mode must be enabled to ensure that the client processes the data correctly and it isn't buffered a line at a time. If this mode is disabled, then the data exchanged between the client and server will be buffered a line at a time and any 8bit characters will be stripped. This mode is enabled by default.

Command Processing

The Telnet protocol can be used to connect to a server, log in and execute one or more commands, process the output from those commands and display it to an end-user using a graphical interface. The user never sees or interacts with the actual terminal session. The Telnet API provides functions which can simplify this kind of application, reducing the amount of code needed to process the data stream returned by the server.

[TelnetLogin](#)

This function is used to automatically log a user in, using the specific user name and password. This function is specifically designed for UNIX based servers or Windows servers which emulate the same basic login sequence.

[TelnetSearch](#)

This function is used to search for a specific character or sequence of characters in the data stream returned by the server. The library will accumulate all of the data received up to the point where the character sequence is encountered. This can be used to capture all of the output from a command, or search for specific results returned by the command as it executes on the server.

Terminal Emulation

The Terminal Emulation library provides a virtual terminal interface for emulating an ANSI or DEC VT-220 compatible character-based terminal. It can be used in conjunction with the Telnet API or the Remote Command API to display the output of commands executed on a server. It can also be used independently of any other networking library, such as providing emulation services for a serial connection.

The first step your application must take is to initialize the library, and then create a virtual display which is attached to a window. The following functions are available for use by your application:

[NvtInitialize](#)

Initialize the library for the current process. This must be the first function call the application makes before calling the other emulator API functions.

[NvtCreateDisplay](#)

Creates a new virtual display and returns a handle which can be used to reference that display. When creating the display, you provide a handle to a window the display will draw on, a handle to a font that will be used to display text characters, the type of emulation and the size of the display.

[NvtDestroyDisplay](#)

Destroy the virtual display, releasing the memory allocated for the handle. After this function returns, the display handle is no longer valid.

[NvtUninitialize](#)

Release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Display Management

The library provides functions to manage and update the virtual display, including a number of lower level functions that provide direct access to the display buffer. The most commonly used functions are:

[NvtWriteDisplay](#)

This is the most commonly used method of writing to the display. This function will automatically parse the data being written for escape sequences and update the display appropriately.

[NvtUpdateDisplay](#)

This function updates the window attached to the virtual display. This function should be called whenever a WM_PAINT message is received for that window, indicating that it needs to be redrawn. The window paint message can be handled in one of two general ways. The simplest is to just call **NvtUpdateDisplay** and return. The function will automatically acquire a device context for the window, redraw the portions of the window that need to be updated, and then release the device context. If you use this method, you should not call **BeginPaint** or **EndPaint**, since that is being done for you. If you wish to acquire the device context yourself by calling **BeginPaint**, then you must call **NvtSetDisplayDC** to attach the device context to the virtual display. When **NvtUpdateDisplay** is called, it will use that device context rather than acquiring one itself. After the display has been updated and you've called **EndPaint**, you should call **NvtSetDisplayDC** again, passing the function a null handle to detach the display from the device context that you've created.

[NvtRefreshDisplay](#)

Refresh the virtual display, updating the current cursor position and caret. The library will periodically refresh the display automatically based on its own internal state, but the application can call this if it wishes to force the display to refresh at that time.

[NvtSetDisplayEmulation](#)

This function can be used to change the emulation used by the library. Supported emulation types are

standard ANSI, DEC VT-100 and VT-200. It is also possible to specify that no emulation should be used, in which case the application is responsible for handling any control or escape sequences in the data being written to the display.

[NvtResetDisplay](#)

This function can be used to change the handle of the window associated with the display, the font being used and the size of the display. Resetting the display causes the contents of the display to be cleared.

[NvtSetDisplayFont](#)

This function sets the font which is used by the library to draw text on the display window. If you wish to specify a font name and point size instead of creating a font handle, use the **NvtSetDisplayFontName** function instead.

[NvtSetDisplayMode](#)

The emulation library has a number of modes which determines how the data is displayed, as well as controlling aspects of the window itself. This function can be used to enable or disable those modes as necessary. For the list of available modes, please consult the Technical Reference.

[NvtSetDisplayColor](#)

This function controls what colors are used when drawing the background of the display window as well as the default color of the text. In ANSI and VT-220 emulation, the color of individual characters can be specified by using escape sequences. Those colors can be modified by changing the display color map.

[NvtSetDisplayColorMap](#)

This function changes the default colors which are used when escape sequences are used to change the foreground or background color of a character cell. In most cases the default color map will be appropriate, but applications can change the RGB values associated with an entry in the color map if needed. For example, the default value for the color gray is at position 8 in the color map index with an RGB value of 192,192,192. If you wanted to use a darker color, you could change the RGB value 128,128,128.

Cursor Control

There are a number of lower level functions which enable an application to have direct control over cursor positioning, clearing the display and so on. In most cases these functions are called automatically by the library as the result of processing the control and escape sequences found in the data being written to the display. However, an application can call these functions directly in order to manage the display itself. One important thing to keep in mind is that the X,Y positions used by these functions refer to the cursor position in the virtual display and correspond to columns and rows, not pixels.

There is also a slight difference in terminology that you should be aware of when reading the technical reference documentation. In Windows, the term "cursor" is typically used to refer to the mouse pointer, while "caret" is used to refer to the blinking marker that is displayed at the current position in the display. In the documentation for the emulator API, the term "cursor" is used in the same way that it is used for character based terminals, as the marker for the current position in the display. Therefore, in terms of the emulation API, you can think of the cursor and the caret as being synonymous.

[NvtGetCursorPos](#)

Return the current position of the cursor in the virtual display.

[NvtSetCursorPos](#)

Change the current position of the cursor in the virtual display. This function will normalize the X,Y values to be bound by the size of the display. If a scrolling region has been set, the coordinates will be bound by that region. The upper left corner of the display is 0,0.

[NvtSaveCursor](#)

Saves the current position of the cursor. The cursor position can be restored by calling the **NvtRestoreCursor** function.

[NvtClearDisplay](#)

Clear the contents of the display. You can clear from the start of the display to the current cursor position, from the current position to the end of the display or the entire display.

[NvtDeleteChar](#)

This function deletes a character from the current cursor position, shifting the remaining characters on the line to the left.

[NvtDeleteLine](#)

This function deletes the line at the current cursor position, shifting the remaining lines in the display up.

[NvtEraseChar](#)

This function erases a character at the current cursor position without affecting the characters that follow it on the line.

[NvtEraseLine](#)

This function erases the line at the current cursor position without affecting the lines that follow it.

[NvtInsertChar](#)

Insert a character at the current cursor position, shifting the following characters to the right.

[NvtInsertLine](#)

Insert a blank line at the current cursor position, shifting the following lines down.

[NvtGetDisplayAttributes](#)

Return the current attributes which have been enabled. Possible attributes are reverse, bold, dim, underline, hidden and protected. These correspond to the attributes that are commonly used with character based terminals.

[NvtSetDisplayAttributes](#)

Set the default attributes which are used when characters are written to the display. For example, setting the attribute NVT_ATTRIBUTE_REVERSE would cause all subsequent characters to be displayed with the foreground and background colors reversed. This would continue until the display attributes were set back to NVT_ATTRIBUTE_NORMAL.

Function Key Mapping

Another aspect of terminal emulation is how function keys and other special keys are handled by the application. The emulation library provides functions which will convert Windows virtual key codes into the escape sequences that are generated by character based terminals.

[NvtTranslateMappedKey](#)

This function translates a virtual key code into the escape sequence which should be sent to the server to emulate pressing that key. For example, if the user presses the F1 key on the keyboard, this will generate a WM_KEYDOWN event with VK_F1 as the virtual key code. This function will translate that key code into the three characters escape sequence ESC O P (the ASCII codes 27, 79, 80). That sequence of characters should be sent to the server, which will recognize it as the F1 function key being pressed. It is important to note that the different emulation types have different key mappings. Therefore, the server must be set to recognize the same type of terminal that you are emulating. If you have the emulation set as VT-220 but the server thinks that you are emulating a VT-100, it will not recognize some of the escape sequences correctly.

[NvtGetMappedKey](#)

Returns the escape sequence associated with a specific function key or special key. There are a total of 50 special keys recognized by the emulator. They consist of the F1 through F12 function keys, the function keys when they are in a shift state, the arrow keys and the keypad keys. Refer to the technical reference for the complete list.

[NvtSetMappedKey](#)

Change the escape sequence associated with a specific function key or special key. Changing this value will cause **NvtTranslateMappedKey** to return the new escape sequence when that key is pressed. This function can also be used to restore the default mapping for a key.

Windows Messages

Because the emulation library is closely tied to a display window, it is important to understand how Windows messages should be handled. If you are not familiar with how Windows processes messages at the API level, it is recommended that you review the technical reference material available from Microsoft on user interface programming. Another excellent resource is "Programming Windows" by Charles Petzold. If you are a C++ programmer, the equivalent MFC virtual functions will also be listed here.

WM_CREATE

This message is sent when the window is being created, but before it is displayed. This is typically a good point to call the **NvtCreateDisplay** function to create the virtual display and attach it to the window. You can also call **NvtSetDisplayMode** to set the various display modes, such as whether you want scrollbars to be shown, what kind of caret should be used and so on. In MFC, this can be done in the Create method for the window.

WM_DESTROY

This message is sent when a window is being destroyed. The application should call **NvtDestroyDisplay** at this point, since the window will no longer exist after the event handler returns.

WM_PAINT

This message is sent when the window needs to be redrawn. This is where the **NvtUpdateDisplay** function should be called. If you are using MFC, the code should be placed in the OnPaint method.

WM_HSCROLL and **WM_VSCROLL**

This message is sent when the user interacts with the window's scrollbars. An application should call the **NvtSetDisplayScrollPos** function to update the scroll position in the virtual display. In MFC, this code should be implemented in the **OnHScroll** and **OnVScroll** methods.

WM_KEYDOWN

This message is sent when the user presses a key. To determine if the key is mapped to a special escape sequence that should be sent to the server, call the **NvtTranslateMappedKey** function. In MFC, this code should be implemented in the **OnKeyDown** method.

WM_SETFOCUS and **WM_KILLFOCUS**

This message is sent when the window acquires or loses focus. You should call **NvtSetDisplayFocus** so that the library knows that the input focus has changed. In MFC, this code should be implemented in the **OnSetFocus** and **OnKillFocus** methods.

WM_SIZE

This message is sent when the window size changes. The application should call the **NvtResizeDisplay** function so that the virtual display is aware that the window size has changed. In MFC, this code should be implemented in the **OnSize** method.

When writing a terminal emulation program, it will also be necessary to handle other Windows messages such as WM_CHAR to process keys pressed by the user, which should be sent to the server. It is recommended that you refer to the Terminal sample program which demonstrates how these messages can be handled by an application. It also serves as a good example of how the Terminal Emulation API can be used in conjunction

with the Telnet API.

Text Message Library

Short Message Service (SMS) is a text messaging service used by mobile communication devices to exchange brief text messages. Most service providers also provide gateway servers that can be used to send messages to a wireless device on their network using standard email protocols. The Text Message API provides functions that can be used to determine the provider associated with a specific telephone number and send a text message to the device using the provider's mail gateway.

The first step your application must take is to initialize the library, which will load the required system libraries and initialize the internal data structures that are used. You must call the initialization function before attempting to call any other function in the library.

[SmsInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other SMS API functions.

[SmsUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Text Messages

Sending a text message is done with a single function call, with two parameters. The first parameter is a pointer to a data structure that identifies the service that will be used to send the message. By default, messages are sent via an SMTP gateway, however the API was designed to be extensible so that additional methods could be integrated into future versions of the library. For example, a third-party company may offer a service that allows messages to be sent using HTTP and that can be added as an additional service type. The second parameter is a pointer to a data structure that contains information about the text message itself.

[SmsSendMessage](#)

This function is used to send the text message. The caller must populate two data structures that contain information about the service provider and the contents of the message itself. The [SMSSERVICE](#) structure is used to provide information about the service being used to send the message, and the [SMSMESSAGE](#) structure is used to provide the function with information about the message.

Service Providers

When a service provider is mentioned in the documentation, typically it is referring to the wireless service provider (also commonly called a "carrier") that is responsible for providing network access for the mobile device. These are identified by name, such as "Verizon Wireless" and "AT&T Mobility". The library has a built-in table of known providers in North America, and can return this information to your application. Note that in some cases, a service provider may also refer to a specific service used to send a text message.

[SmsGetProvider](#)

This function returns information about the wireless service provider that is associated with a specific phone number. This can be used to determine if a phone number is valid, and the default provider that is responsible for that number. Information about the service provider is returned in an [SMSPROVIDER](#) structure.

[SmsEnumProviders](#)

This function enumerates all of the supported wireless service providers and populates an array of structures that contain information about each provider. Typically this is used to update the user interface with a list of known service providers, allowing the end-user to select a specific service provider.

[SmsGetFirstProvider](#) and [SmsGetNextProvider](#)

These functions are also used to enumerate the supported wireless service providers, but they return information about a single provider with each function call. They are primarily designed to be used with languages that don't provide an easy way to work with an array of data structures. The information that is returned is identical to the **SmsEnumProviders** function.

Gateway Servers

A gateway server refers to the server that is responsible for accepting the text message and sending it to the recipient. Currently, this is exclusively used in the context of SMTP gateways where the message is sent to a mail server operated by the wireless service provider.

[SmsGetGateway](#)

This function returns information about the gateway that is responsible for accepting a text message for a specific phone number and forwarding that message to the mobile device. Information about the gateway is returned in an [SMSGATEWAY](#) structure.

Time Protocol

The Time protocol library enables an application to retrieve the current time from a server, and optionally synchronize the local system time using that value. The first step that your application must take is to initialize the library. After the library has been initialized, the application can request the current time from a system and update the local system clock if necessary.

TimeInitialize

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call that the application makes before calling the other Time API functions.

GetNetworkTime

Return the current time from a server. The time is expressed as a 32-bit integer value which represents the number of seconds since midnight, 1 January 1900 UTC.

UpdateLocalTime

Update the local system time with the value returned by **GetNetworkTime**. This function requires that the current user have the appropriate permissions to modify the system time or the function will fail.

TimeUninitialize

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Time Conversion

Windows applications typically use a structure called **SYSTEMTIME** to represent date and time values. The library has two functions which will enable you to convert between the value returned by **GetNetworkTime** and the **SYSTEMTIME** structure.

ConvertNetworkTime

This function will convert the value returned by **GetNetworkTime** into a **SYSTEMTIME** structure, adjusting for the local timezone if required.

ConvertSystemTime

This function will convert a **SYSTEMTIME** structure into a 32-bit integer value. This value may be passed to the **UpdateLocalTime** function to update the local system clock.

Whois Protocol

The Whois protocol library provides an interface for requesting information about an Internet domain name. When a domain name is registered, the organization that registers the domain must provide certain contact information along with technical information such as the primary name servers for that domain. The Whois protocol enables an application to query a server that provides that registration information. The Whois library provides an API for requesting that information and returning it to the program so it can be displayed or processed.

The first step your application must take is to initialize the library and then establish a connection. The following functions are available for use by your application:

[WhoisInitialize](#)

Initialize the library and load the Windows Sockets library for the current process. This must be the first function call the application makes before calling the other Whois API functions.

[WhoisConnect](#)

Connect to the server, using either a host name or IP address. This function returns a client handle which is used in subsequent calls to the library.

[WhoisSearch](#)

Perform a search for a specific domain. The server will return the results of the search as a text document which provides registration information for that domain. It is important to note that different registrars may use different formats when returning the data, and not all servers return the same type of information.

[WhoisRead](#)

Read the data returned by the server. Your application would typically call this function in a loop until all of the data has been read or an error occurs.

[WhoisDisconnect](#)

Disconnect from the server and release the memory allocated for that client session. After this function is called, the client handle is no longer valid.

[WhoisUninitialize](#)

Unload the Windows Sockets library and release any resources that have been allocated for the current process. This is the last function call the application should make prior to terminating.

Domain Name Service Class Library

Resolve domain names into Internet addresses and return information about a remote host, such as the servers that are responsible for accepting mail for the domain.

Library Information

Class Name	CDnsClient
File Name	CSDNSV11.DLL
Version	11.0.2218.1855
LibID	D0B892B2-2930-4919-BED9-BD494D65BDBB
Import Library	CSDNSV11.LIB
Dependencies	None
Standards	RFC 1034

Overview

The Domain Name Services (DNS) protocol is what applications use to resolve domain names into Internet addresses as well as provide other information about a domain. All of the SocketTools libraries provide basic domain name resolution functionality, but the Domain Name Services library gives an application direct control over what servers are queried, the amount of time spent waiting for a response and the type of information that is returned.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX

component, and does not require COM registration.

Domain Name Service Class Methods

Class	Description
CDnsClient	Constructor which initializes the current instance of the class
~CDnsClient	Destructor which releases resources allocated by the class
Method	Description
AttachHandle	Attach the specified client handle to this instance of the class
AttachThread	Attach the specified client handle to another thread
Cancel	Cancel an outstanding nameserver query
DetachHandle	Detach the handle for the current instance of this class
DisableTrace	Disable logging of network function calls to the trace log
EnableTrace	Enable logging of network function calls to a file
EnumHostAliases	Enumerate the aliases for the specified host name or address
EnumMailExchanges	Return a list of mail exchanges for the specified host name or IP address
FormatAddress	Convert a numeric IPv4 address to a string
GetAddress	Convert an address string in dotted notation to a numeric IPv4 address
GetAddressFamily	Return the address family for the specified IP address
GetDefaultHostFile	Return the full path to the default host file on the local system
GetDefaultServicesFile	Return the full path to the default services file on the local system
GetErrorString	Return a description for the specified error code
GetHandle	Return the client handle used by this instance of the class
GetHostAddress	Return the IP address of the specified hostname
GetHostByAddress	Return a pointer to data for the specified host IP address
GetHostByName	Return a pointer to data for the specified host name
GetHostFile	Return the name of the current host file
GetHostInfo	Return additional information for the specified host
GetHostName	Return the host name for the specified IP address
GetHostServices	Return a list of services supported by the specified host
GetLastError	Return the last error code
GetLocalAddress	Return the IP address for the local host
GetLocalDomain	Return the local domain name for the current session
GetLocalName	Return the local host name
GetMailExchange	Return the host that processes mail for the specified domain
GetRecord	Return record data for the current host
GetResolverAddress	Return address of last nameserver that resolved query

GetResolverOptions	Return the current resolver options for the client session
GetRetryCount	Get the number of times the query is sent to each server
GetServerAddress	Return the address of the specified nameserver
GetServerPort	Return the port of the specified nameserver
GetServiceName	Return the name of a service assigned to the specified port number
GetServicePort	Return the port number assigned to the specified service name
GetTimeout	Get the number of seconds until a query times out
HostNameToUnicode	Converts the canonical form of a host name to its Unicode version
IsInitialized	Determine if the class has been successfully initialized
MatchHostName	Match a host name against of list of addresses including wildcards
NormalizeHostName	Return the canonical form of a host name
RegisterServer	Add a nameserver address to the current session
Reset	Reset the current client state
Resolve	Resolve a host name into an IP address or an IP address into a host name
SetHostFile	Specify the name of an alternate file to use when resolving host names and IP addresses
SetLastError	Set the last error code
SetLocalDomain	Set the local domain name for the current session
SetResolverOptions	Set the resolver options for the client session
SetRetryCount	Set the number of times the query is sent to each server
SetTimeout	Set the number of seconds until a query times out
ShowError	Display a message box with a description of the specified error
UnregisterServer	Remove a nameserver address from the current session

CDnsClient::CDnsClient Method

CDnsClient();

The **CDnsClient** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **DnsInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnsv11.lib

See Also

[~CDnsClient](#), [IsInitialized](#), [SetResolverOptions](#)

CDnsClient::~~CDnsClient

~CDnsClient();

The **CDnsClient** destructor releases resources allocated by the current instance of the CDnsClient object. It also uninitialized the library if there are no other concurrent uses of the class.

Remarks

When a **CDnsClient** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CDnsClient](#)

CDnsClient::AttachHandle Method

```
VOID AttachHandle(  
    HCLIENT hClient  
);
```

The **AttachHandle** method attaches the specified client handle to the current instance of the class.

Parameters

hClient

The handle to the client session that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a client handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that client session.

If a client handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous client session from being terminated, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hClient* parameter is presumed to be a valid client handle and no checks are performed to ensure that the handle is valid. Specifying an invalid client handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

See Also

[DetachHandle](#), [GetHandle](#)

CDnsClient::AttachThread Method

```
DWORD AttachThread(  
    DWORD dwThreadId  
);
```

The **AttachThread** method attaches the specified client handle to another thread.

Parameters

dwThreadId

The ID of the thread that will become the new owner of the class. A value of zero specifies that the current thread should become the owner of the class instance.

Return Value

If the method succeeds, the return value is the thread ID of the previous owner. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

When a client handle is created, it is associated with the current thread that created it. Normally, if another thread attempts to perform an operation using that handle, an error is returned since it does not own the handle. This is used to ensure that other threads cannot interfere with an operation being performed by the owner thread. In some cases, it may be desirable for one thread in a client application to create the client handle, and then pass that handle to another worker thread. The **AttachThread** method can be used to change the ownership of the handle to the new worker thread. By preserving the return value from the method, the original owner of the handle can be restored before the worker thread terminates.

This method should be called by the new thread immediately after it has been created, and if the new thread does not release the handle itself, the ownership of the handle should be restored to the parent thread before it terminates. Under no circumstances should **AttachThread** be used to forcibly release a handle allocated by another thread while a blocking operation is in progress. To cancel an operation, use the **Cancel** method and then release the handle after the blocking method exits and control is returned to the current thread.

Note that the *dwThreadId* parameter is presumed to be a valid thread ID and no checks are performed to ensure that the thread actually exists. Specifying an invalid thread ID will orphan the client handle used by the class until the destructor is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

See Also

[AttachHandle](#), [Cancel](#)

CDnsClient::Cancel Method

```
INT Cancel();
```

The **Cancel** method cancels any outstanding queries initiated by the client.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is DNS_ERROR.

To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

See Also

[GetHostByAddress](#), [GetHostByName](#), [GetHostInfo](#), [GetHostServices](#), [GetMailExchange](#), [GetRecord](#)

CDnsClient::DetachHandle Method

HCLIENT DetachHandle();

The **DetachHandle** method detaches the client handle associated with the current instance of the class.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to detach a client handle created by the class for use with the SocketTools API. Once the client handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CDnsClient::DisableTrace Method

BOOL DisableTrace();

The **DisableTrace** method disables the logging of socket function calls to the trace log.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnableTrace](#)

CDnsClient::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of socket function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the remote host.

Trace method logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdntsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisableTrace](#)

CDnsClient::EnumHostAliases Method

```
INT EnumHostAliases(  
    LPCTSTR lpszHostName,  
    LPTSTR *lpszHostAlias,  
    INT nMaxAliases  
);
```

The **EnumHostAliases** method returns a list of aliases for the specified host name or IP address.

Parameters

lpszHostName

Pointer to the string that contains the hostname to be resolved. If a fully qualified domain name is not provided, the default local domain will be used. This value may also be an IP address.

lpszHostAlias

Pointer to an array of string pointers which specify one or more host aliases. If the application needs to store these values, a local copy should be made because they are invalidated when another host name is resolved.

nMaxAliases

The maximum number of aliases in the array. This parameter must have a value of at least one, or an error will be returned.

Return Value

If the method succeeds, the return value is the number of host aliases. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The application must never attempt to modify the host aliases or delete any of the values. This method uses an internal data structure to store the host information and only one copy of this structure is allocated per thread. The application must copy any information it needs before issuing any other function calls.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostAddress](#), [GetHostName](#)

CDnsClient::EnumMailExchanges Method

```
INT EnumMailExchanges(  
    LPCTSTR lpszHostName,  
    LPTSTR *lpszMailExchanges,  
    INT nMaxMailExchanges  
);
```

The **EnumMailExchanges** method returns a list of mail exchanges for the specified host name or IP address.

Parameters

lpszHostName

Pointer to the string that contains the hostname or domain name to be queried.

lpszMailExchanges

Pointer to an array of string pointers which specify one or more mail exchanges. If the application needs to store these values, a local copy should be made because they are invalidated when another host name is resolved. The list of mail exchange records is sorted in priority order, from highest (i.e., those whose preference value is smallest) to lowest.

nMaxMailExchanges

The maximum number of mail exchanges in the array. If this parameter is 0, then the method will return the number of mail exchanges, but the list of mail exchanges will not be output in

lpszMailExchanges.

Return Value

If the method succeeds, the return value is the number of mail exchanges. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The application must never attempt to modify the mail exchange host names or delete any of the values. This method uses an internal data structure to store the host information and only one copy of this structure is allocated per thread. The application must copy any information it needs before issuing any other method calls.

Example

```
// Get the number of mail exchanges  
if ((nMX = pClient->EnumMailExchanges(szHostName, NULL, 0)) == DNS_ERROR)  
{  
    pClient->ShowError();  
}  
else  
{  
    // Allocate memory for the list of mail exchanges  
    lpszMailExchanges = (LPTSTR *)LocalAlloc(LPTR, (nMX * sizeof(LPTSTR)));  
  
    // Retrieve the list of mail exchanges  
    nMX = pClient->EnumMailExchanges(szHostName, lpszMailExchanges, nMX);  
  
    // Populate a listbox with the mail exchanges  
    for (int nIndex = 0; nIndex < nMX; nIndex++)  
        pListBox->AddString(*lpszMailExchanges++);  
  
    LocalFree((HLOCAL)lpszMailExchanges);  
}
```

}

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnav11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetMailExchange](#)

CDnsClient::FormatAddress Method

```
INT FormatAddress(  
    LPINTERNET_ADDRESS LpAddress,  
    LPTSTR LpszAddress,  
    INT nMaxLength  
);  
  
INT FormatAddress(  
    LPINTERNET_ADDRESS LpAddress,  
    CString& strAddress  
);
```

The **FormatAddress** method converts a numeric IPv4 or IPv6 address to a string.

Parameters

lpAddress

A pointer to an INTERNET_ADDRESS structure which specifies the numeric IPv4 or IPv6 address to be converted into a string.

lpszAddress

A pointer to a null-terminated array of characters which will contain the converted IPv4 address in dot-notation. This string should be at least 16 characters in length. If the Microsoft Foundation Classes are being used, the second form of this method may be called where a **CString** object is specified instead.

nMaxLength

The maximum number of characters which may be copied in to the string buffer.

Return Value

If the method succeeds, the return value is the length of the string buffer. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetAddress](#), [GetHostAddress](#), [GetHostInfo](#), [GetHostServices](#), [GetMailExchange](#), [GetRecord](#), [INTERNET_ADDRESS](#)

CDnsClient::GetAddress Method

```
INT GetAddress(  
    LPCTSTR lpszAddress,  
    INT nAddressFamily,  
    LPINTERNET_ADDRESS lpAddress  
);
```

The **GetAddress** method converts an address string to a numeric IPv4 or IPv6 address.

Parameters

lpszAddress

A pointer to a string which specifies an IPv4 address in dotted notation.

nAddressFamily

An integer value which specifies the type of IP address. If this parameter is zero, the address family will be determined automatically based on the format of the address string. If this parameter is DNS_ADDRESS_IPV4, the address must be in IPv4 format, and if it is DNS_ADDRESS_IPV6, the address must be in IPv6 format.

lpAddress

A pointer to an INTERNET_ADDRESS structure that will contain the numeric form of the IPv4 or IPv6 address in network byte order when the method returns.

Return Value

If the method succeeds, the return value is the address family for the IP address. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method will only accept a string that is in the proper format for an IP address, and cannot be used to resolve a host name. To perform host name resolution, use the **GetHostAddress** method. To convert a numeric address to an address string, use the **FormatAddress** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[FormatAddress](#), [GetHostAddress](#), [GetHostInfo](#), [GetHostServices](#), [GetMailExchange](#), [GetRecord](#), [INTERNET_ADDRESS](#)

CDnsClient::GetAddressFamily Method

```
INT GetAddressFamily(  
    LPCTSTR lpszAddress  
);
```

The **GetAddressFamily** method returns the address family for the specified IP address.

Parameters

lpszAddress

A pointer to a string which specifies an IPv4 or IPv6 address.

Return Value

If the method succeeds, the return value is DNS_ADDRESS_IPV4 if the address is in IPv4 format, or DNS_ADDRESS_IPV6 if the address is in IPv6 format. If the address string is not in a recognized format, it returns DNS_ADDRESS_UNKNOWN.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DnsGetHostAddress](#), [DnsGetHostInfo](#), [DnsGetHostServices](#), [DnsGetMailExchange](#), [DnsGetRecord](#)

CDnsClient::GetDefaultHostFile Method

```
INT GetDefaultHostFile(  
    LPTSTR lpszFileName,  
    INT nMaxLength  
);  
  
INT GetDefaultHostFile(  
    CString& strFileName  
);
```

The **GetDefaultHostFile** method returns the fully qualified path name of the host file on the local system. The host file is used as a database that maps an IP address to one or more hostnames, and is used by the **GetHostAddress** and **GetHostName** methods. The file is a plain text file, with each line in the file specifying a record, and each field separated by spaces or tabs. The format of the file must be as follows:

```
ipaddress hostname [hostalias ...]
```

For example, one typical entry maps the name "localhost" to the local loopback IP address. This would be entered as:

```
127.0.0.1 localhost
```

The hash character (#) may be used to specify a comment in the file, and all characters after it are ignored up to the end of the line. Blank lines are ignored, as are any lines which do not follow the required format.

Parameters

lpszFileName

Pointer to a string buffer that will contain the fully qualified file name to the default host file. It is recommended that this buffer be at least MAX_PATH characters in size. This parameter may be NULL, in which case the method will return the length of the string, not including the terminating null byte. An alternative version of this method accepts a **CString** object.

nMaxLength

The maximum number of characters that may be copied to the string buffer.

Return Value

If the function succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. A return value of zero indicates that the default host file could not be determined for the current platform. To get extended error information, call **GetLastError**.

Remarks

This method returns the location of the host file and does not determine if the file actually exists. The default location for this file is in a protected area of the Windows operating system and can only be modified by a process with administrative privileges.

The default host file is processed before performing a nameserver lookup when resolving a hostname into an IP address, or an IP address into a hostname. To specify an alternate local host file, use the **SetHostFile** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetDefaultServicesFile](#), [GetHostAddress](#), [GetHostFile](#), [GetHostName](#), [SetHostFile](#)

CDnsClient::GetDefaultServicesFile Method

```
INT GetDefaultServicesFile(  
    LPTSTR lpzFileName,  
    INT nMaxLength  
);  
  
INT GetDefaultServicesFile(  
    CString& strFileName  
);
```

The **GetDefaultServicesFile** method returns the fully qualified path name of the services file on the local system. The services file is used as a database that maps a port number to a service name, and is used by the **GetServiceName** and **GetServicePort** methods. The file is a plain text file, with each line in the file specifying a record, and each field separated by spaces or tabs. The format of the file must be as follows:

name port/protocol [alias ...]

For example, one typical entry maps the service name "http" to port 80, the standard port for the Hypertext Transfer Protocol. This would be entered as:

http 80/tcp www www-http

The hash character (#) may be used to specify a comment in the file, and all characters after it are ignored up to the end of the line. Blank lines are ignored, as are any lines which do not follow the required format.

Parameters

lpzFileName

Pointer to a string buffer that will contain the fully qualified path to the default services file. It is recommended that this buffer be at least MAX_PATH characters in size. This parameter may be NULL, in which case the function will return the length of the string, not including the terminating null byte. An alternative version of this method accepts a **CString** object.

nMaxLength

The maximum number of characters that may be copied to the string buffer.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. A return value of zero indicates that the default services file could not be determined for the current platform. To get extended error information, call **GetLastError**.

Remarks

This method returns the location of the services file and does not determine if the file actually exists. The default location for this file is in a protected area of the Windows operating system and can only be modified by a process with administrative privileges.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT nMaxLength  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The last-error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length.

nMaxLength

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is 0, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLastError](#), [SetLastError](#), [ShowError](#)

CDnsClient::GetHandle Method

```
HCLIENT GetHandle();
```

The **GetHandle** method returns the client handle associated with the current instance of the class.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to obtain the client handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

See Also

[AttachHandle](#), [DetachHandle](#), [IsInitialized](#)

CDnsClient::GetHostAddress Method

```
INT GetHostAddress(  
    LPCTSTR lpszHostName,  
    INT nAddressFamily,  
    LPTSTR lpszHostAddress,  
    INT nMaxLength  
);  
  
INT GetHostAddress(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszHostAddress,  
    INT nMaxLength  
);  
  
INT GetHostAddress(  
    LPCTSTR lpszHostName,  
    INT nAddressFamily,  
    CString& strHostAddress  
);  
  
INT GetHostAddress(  
    LPCTSTR lpszHostName,  
    CString& strHostAddress  
);
```

The **GetHostAddress** method resolves the specified host name, storing the IP address in the provided buffer.

Parameters

lpszHostName

Pointer to the string that contains the hostname to be resolved. If a fully qualified domain name is not provided, the default local domain will be used.

nAddressFamily

An integer value which specifies the type of address that should be returned. A value of DNS_ADDRESS_IPV4 specifies that the IPv4 address for the host should be returned. A value of DNS_ADDRESS_IPV6 specifies that the IPv6 address for the host should be returned. A value of DNS_ADDRESS_ANY specifies that if the host only has an IPv6 address, that value should be returned, otherwise return the IPv4 address for the host. There are alternate versions of this method which omits the address family, in which case it will default to returning the IPv4 address for the host.

lpszHostAddress

Pointer to the buffer that will contain the IP address, stored as a string in dot notation. This buffer should be at least 48 characters in length. The format of the address is determined by the address family specified.

nMaxLength

The maximum length of the string buffer. The maximum length of the buffer must include the terminating null character.

Return Value

If the method succeeds, the return value is the number of characters copied into the host address buffer. If the method fails, the return value is DNS_ERROR. To get extended error information, call

GetLastError.

Remarks

The **GetHostAddress** method may return an address in either IPv4 or IPv6 format, depending on the address family that is specified and what records exist for the host. If your application does not support the IPv6 address format, you must specify the *nAddressFamily* parameter as `DNS_ADDRESS_IPV4` to prevent the possibility of an IPv6 address being returned.

If the *nAddressFamily* parameter is specified as `DNS_ADDRESS_ANY`, this function will first check for an IPv4 address record for the host. If it exists, it will return that address. If the host does not have an IPv4 address, it will then check for an IPv6 address record and return that address. This gives preference to IPv4 addresses, but your application should never depend on this behavior. In the future, this function may change to give preference to IPv6 addresses.

To determine what format an address is in, use the **GetAddressFamily** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnumHostAliases](#), [GetAddressFamily](#), [GetHostName](#), [GetRecord](#)

CDnsClient::GetHostByAddress Method

```
LPHOSTENT GetHostByAddress(  
    LPVOID LpvAddress,  
    INT cbAddress,  
    INT nAddressFamily  
);
```

The **GetHostByAddress** method returns a pointer to a [HOSTENT](#) structure which contains the results of a successful search for the host specified by address parameter.

Parameters

lpvAddress

Pointer to an integer IPv4 address in network byte order.

cbAddress

The length of the address in bytes; this value should always be 4.

nAddressFamily

The type of address being resolved; this value should always be DNS_ADDRESS_IPV4 as defined in the Windows Sockets header file.

Return Value

If the method succeeds, the return value is a pointer to a HOSTENT structure. If the method fails, the return value is NULL. To get extended error information, call **GetLastError**.

Remarks

The application must never attempt to modify this structure or to free any of its components. Only one copy of this structure is allocated per thread, so the application should copy any information it needs before issuing any other function calls. To convert an IPv4 address string in dotted notation to a 32-bit IP address, use the **GetAddress** method.

This method is included for compatibility with existing applications which already use the HOSTENT structure. Because this method returns a pointer to a complex structure, it may not be suitable for some programming languages. There is no Unicode version of the HOSTENT structure and members will return pointers to ANSI strings even if the application is compiled to use Unicode.

This method is not compatible with IPv6 addresses. For applications that must support both IPv4 and IPv6 address formats, use the **GetHostAddress** and **GetHostName** methods.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostAddress](#), [GetHostByName](#), [GetHostInfo](#), [GetHostName](#), [GetHostServices](#), [GetRecord](#), [GetResolverAddress](#), [RegisterServer](#)

CDnsClient::GetHostByName Method

```
LPHOSTENT GetHostByName(  
    LPCTSTR lpszHostName  
);
```

The **GetHostByName** method returns a pointer to a [HOSTENT](#) structure which contains the results of a successful search for the host specified in the name parameter.

Parameters

lpszHostName

Pointer to the string that contains the hostname to be resolved. If a fully qualified domain name is not provided, the default local domain will be used.

Return Value

If the method succeeds, the return value is a pointer to a HOSTENT structure. If the method fails, the return value is NULL. To get extended error information, call **GetLastError**.

Remarks

The application must never attempt to modify this structure or to free any of its components. Only one copy of this structure is allocated per thread, so the application should copy any information it needs before issuing any other function calls. This method will automatically resolve an IP address passed as a string, converting it to numeric form and calling the **GetHostByAddress** method.

This method is included for compatibility with existing applications which already use the HOSTENT structure. Because this function returns a pointer to a complex structure, it may not be suitable for some programming languages. There is no Unicode version of the HOSTENT structure and members will return pointers to ANSI strings even if the application is compiled to use Unicode.

This method is not compatible with IPv6 addresses. For applications that must support both IPv4 and IPv6 address formats, use the **GetHostAddress** and **GetHostName** methods.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostAddress](#), [GetHostByAddress](#), [GetHostInfo](#), [GetHostName](#), [GetHostServices](#), [GetMailExchange](#), [GetRecord](#), [GetResolverAddress](#), [RegisterServer](#)

CDnsClient::GetHostFile Method

```
INT GetHostFile(  
    LPTSTR lpszFileName,  
    INT nMaxLength  
);  
  
INT GetHostFile(  
    CString& strFileName  
);
```

The **GetHostFile** method returns the name of the host file previously set using the **SetHostFile** method. The host file is used as a database that maps an IP address to one or more hostnames, and is used by the **GetHostAddress** and **GetHostName** method.

Parameters

lpszFileName

Pointer to a string buffer that will contain the host file name. It is recommended that this buffer be at least MAX_PATH characters in size. This parameter may be NULL, in which case the method will return the length of the string, not including the terminating null character.

nMaxLength

The maximum number of characters that may be copied to the string buffer.

Return Value

If the method succeeds, the return value is length of the string. A return value of zero indicates that no host file has been specified or the method was unable to determine the file name. To get extended error information, call **GetLastError**. If the last error is zero, this indicates that no host file name has been specified for the current thread. If the last error is non-zero, this indicates the reason that the method failed.

Remarks

This method only returns the name of the host file that is cached in memory for the current thread. The contents of the file on the disk may have changed after the file was loaded into memory. To reload the host file or clear the cache, call the **SetHostFile** method.

If a host file has been specified, it is processed before the default host file when resolving a hostname into an IP address, or an IP address into a hostname. If the host name or address is not found, or no host file has been specified, a nameserver lookup is performed.

The host file returned by this method may be different than the default host file for the local system. To determine the file name for the default host file, use the **GetDefaultHostFile** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CDnsClient::GetHostInfo Method

```
INT GetHostInfo(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

The **GetHostInfo** method returns the HINFO record for the specified hostname. This information, if it is provided, typically specifies the operating system type and hardware platform.

Parameters

lpszHostName

Pointer to the string which specifies the host name that information will be returned for.

lpszBuffer

Pointer to the buffer which will contain the host information returned by the nameserver.

nMaxLength

Maximum number of characters that may be copied into the specified buffer, including the null character terminator.

Return Value

If the method succeeds, the length of the host information buffer is returned. A return value of zero indicates that no information is available for the specified host. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

Many systems do not maintain HINFO records for a site since that information can potentially be used to compromise system security. The information is typically used for administrative purposes with internal networks.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostByAddress](#), [GetHostByName](#), [GetHostServices](#), [GetMailExchange](#), [GetRecord](#),
[GetResolverAddress](#), [RegisterServer](#)

CDnsClient::GetHostName Method

```
INT GetHostName(  
    LPCTSTR lpszHostAddress,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
INT GetHostName(  
    LPCTSTR lpszHostAddress,  
    CString& strHostName  
);
```

The **GetHostName** method resolves the specified IP address, storing the fully qualified host name in the provided buffer.

Parameters

lpszHostAddress

Pointer to a string that specifies an IPv4 or IPv6 formatted address.

lpszHostName

Pointer to the buffer that will contain the fully qualified domain name for the specified host. This buffer should be at least 64 characters in length.

nMaxLength

The maximum length of the string buffer.

Return Value

If the method succeeds, the return value is the number of characters copied into the host name buffer. If the method fails, the return value is `DNS_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **GetHostName** method first looks to see if there is an entry in the local host file for the specified IP address, and if one exists, it will return the host name for that address. If you do not want to use the local host file at all, and only return an host name if a DNS query resolves the address, use the **GetRecord** method and specify a record type of `DNS_RECORD_PTR`.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetHostServices Method

```
INT GetHostServices(  
    LPCTSTR lpszHostName,  
    INT nProtocol,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

The **GetHostServices** method returns the WKS (Well Known Services) record for the specified hostname and protocol. This information, if it is provided, typically specifies the names of those services supported on the host.

Parameters

lpszHostName

Pointer to the string which specifies the host name that information will be returned for.

nProtocol

The protocol for those services that information should be returned about. The following protocols are recognized:

Value	Description
INET_PROTOCOL_TCP	Services that use the Transmission Control Protocol (TCP)
INET_PROTOCOL_UDP	Services that use the User Datagram Protocol (UDP)

lpszBuffer

Pointer to the buffer which will contain the host information returned by the nameserver.

nMaxLength

Maximum number of characters that may be copied into the specified buffer, including the null character terminator.

Return Value

If the method succeeds, the length of the host services buffer is returned. A return value of zero indicates that no information is available for the specified host. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

Many systems do not maintain complete services records for a site since that information can potentially be used to compromise system security. An application should not depend on this information being available for any given record.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or DNS_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnsv11.lib

See Also

[GetErrorString](#), [SetLastError](#), [ShowError](#)

CDnsClient::GetLocalAddress Method

```
INT GetLocalAddress(  
    INT nAddressFamily,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);
```

The **DnsGetLocalAddress** method returns the IP address for the local host.

nAddressFamily

An integer value which specifies the type of address that should be returned. A value of DNS_ADDRESS_IPV4 specifies that the IPv4 address for the host should be returned. A value of DNS_ADDRESS_IPV6 specifies that the IPv6 address for the host should be returned. A value of DNS_ADDRESS_ANY specifies that if the host only has an IPv6 address, that value should be returned, otherwise return the IPv4 address for the host.

lpszAddress

Pointer to the buffer that will contain the IP address, stored as a string in dot notation. This buffer should be at least 40 characters in length to accommodate both IPv4 and IPv6 addresses.

nMaxLength

The maximum length of the string buffer.

Return Value

If the method succeeds, the return value is the number of characters copied into the host address buffer. If the method fails, the return value is DNS_ERROR. To get extended error information, call **DnsGetLastError**.

Remarks

The **GetLocalAddress** method may return an address in either IPv4 or IPv6 format, depending on the address family that is specified and what records exist for the host. If your application does not support the IPv6 address format, you must specify the *nAddressFamily* parameter as DNS_ADDRESS_IPV4 to prevent the possibility of an IPv6 address being returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetLocalDomain Method

```
INT GetLocalDomain(  
    LPTSTR lpszDomain,  
    INT nMaxLength  
);
```

The **GetLocalDomain** method copies the local domain name into the specified buffer. The value returned is the same value that was set with the **SetLocalDomain** method. If no local domain name has been set, an empty string is returned.

Parameters

lpszDomain

Pointer to the buffer that is used to store the local domain name. If no local domain name has been set, this buffer will be set to zero length.

nMaxLength

The maximum number of bytes to copy into the buffer, including the null character terminator.

Return Value

If the method succeeds, the return value is the length of the domain name string. A return value of zero indicates that no local domain name has been set. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetLocalName Method

```
INT GetLocalName(  
    LPTSTR lpszLocalName,  
    INT nMaxLength  
);
```

The **GetLocalName** method returns the local host name.

Parameters

lpszLocalName

Pointer to a string buffer that will contain the local host name. It is recommended that this buffer be at least 64 characters in size.

nMaxLength

The maximum number of characters that may be copied to the string buffer.

Return Value

If the method succeeds, the return value is the length of the local host name. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetMailExchange Method

```
INT GetMailExchange(  
    LPCTSTR lpszHostName,  
    LPINT lpnPreference,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

The **GetMailExchange** method returns the mail exchange (MX) record information for the specified domain. This information, if it is provided, identifies a server responsible for processing mail for the given domain.

Parameters

lpszHostName

Pointer to the string which specifies the host name that information will be returned for.

lpnPreference

Pointer to the integer which will contain the preference for the specified mail exchange host.

lpszBuffer

Pointer to the buffer which will contain the host information returned by the nameserver.

nMaxLength

Maximum number of characters that may be copied into the specified buffer, including the null character terminator.

Return Value

If the method succeeds, the length of the buffer is returned. A return value of zero indicates that no information is available for the specified host. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The mail exchange record is typically used by mail delivery agents to determine what system is responsible for accepting mail addressed to a given domain. This method will return the first MX record provided by the server. Note that some domains may have multiple mail servers. To enumerate all of the mail exchange records for a domain, use the **EnumMailExchanges** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetHostByAddress](#), [GetHostByName](#), [GetHostInfo](#), [GetHostServices](#), [GetRecord](#), [GetResolverAddress](#), [RegisterServer](#), [EnumMailExchanges](#)

CDnsClient::GetRecord Method

```
INT GetRecord(  
    LPCTSTR lpszHostName,  
    INT nRecordType,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);  
  
INT GetRecord(  
    LPCTSTR lpszHostName,  
    INT nRecordType,  
    CString& strBuffer  
);
```

The **GetRecord** method returns the specified record information for the given hostname.

Parameters

lpszHostName

Pointer to the string which specifies the host name that information will be returned for.

nRecordType

The record type for the information that should be returned. The following record types are recognized:

Value	Description
DNS_RECORD_NONE	No record type
DNS_RECORD_ADDRESS	Host address
DNS_RECORD_NS	Authoritative nameserver
DNS_RECORD_CNAME	Canonical name (alias)
DNS_RECORD_SOA	Start of Authority
DNS_RECORD_WKS	Well known services
DNS_RECORD_PTR	Domain name
DNS_RECORD_HINFO	Host information
DNS_RECORD_MINFO	Mailbox information
DNS_RECORD_MX	Mail exchange host
DNS_RECORD_TXT	Text strings
DNS_RECORD_LOC	Location information
DNS_RECORD_UINFO	User information
DNS_RECORD_UID	User ID
DNS_RECORD_GID	Group ID

lpszBuffer

Pointer to the buffer which will contain the host information returned by the nameserver.

nMaxLength

Maximum number of characters that may be copied into the specified buffer, including the null character terminator.

Return Value

If the method succeeds, the length of the information buffer is returned. A return value of zero indicates that no information for that record is available for the specified host. If the method fails, the return value is `DNS_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **GetRecord** method can be used to resolve a host name into an IP address using the record type `DNS_RECORD_ADDRESS`. It can also be used to perform a reverse lookup and resolve an IP address into a host name by using the record type `DNS_RECORD_PTR`.

To determine the host that serves as the primary or master DNS for a zone, the record name should be specified as the domain name (e.g.: `microsoft.com`) and the record type should be `DNS_RECORD_SOA`. The value returned will be the fully qualified domain name for host.

Note that this method does not reference a local host file when resolving host names or addresses. If the record lookup fails, this method will return an error even if there's an entry for the host in the file that has been specified by a call to **SetHostFile**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetResolverAddress Method

```
INT GetResolverAddress(  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetResolverAddress(  
    CString& strAddress  
);
```

The **GetResolverAddress** returns the address of the nameserver that resolved the last query.

Parameters

lpszAddress

A pointer to a string buffer that will contain the address of the nameserver when the function returns. This buffer should be large enough to store both IPv4 and IPv6 addresses, with a minimum length of 40 characters. If this parameter is NULL, it will be ignored.

nMaxLength

The maximum number of characters that can be copied into the string buffer. If this value is zero, the *lpszAddress* parameter will be ignored and the function will return the length of the address.

Return Value

If the method succeeds, the return value is the length of the address, not including the terminating null character. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetResolverOptions Method

DWORD GetResolverOptions();

The **GetResolverOptions** method returns the options that have been set for the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is the resolver options set for the client session. If the client handle is invalid or no resolver options have been specified, the function will return zero.

Remarks

The **GetResolverOptions** method can be used to determine which resolver options have been specified for the client session. For a list of the available options, refer to the documentation for the **SetResolverOptions** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

See Also

[CDnsClient](#), [SetResolverOptions](#)

CDnsClient::GetRetryCount Method

INT GetRetryCount();

The **GetRetryCount** returns the retry count for the current client session.

Return Value

If the method succeeds, the return value is the retry count. If the method fails, the return value is `DNS_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The retry count determines the amount of time the client will wait for a response from each query, the effective amount of time the client will wait increases with each nameserver and the total number of retries specified. For example, two nameservers registered with the client, with a default of 4 retries per nameserver and a timeout value of 10 seconds, would cause the client to wait a total of 80 seconds until it returns an error indicating that it was unable to resolve the query.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetServerAddress Method

```
INT GetServerAddress(  
    INT nServer,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetServerAddress(  
    INT nServer,  
    CString& strAddress  
);
```

The **GetServerAddress** method returns the address of the specified nameserver.

Parameters

nServer

The index into the client's nameserver table. This index is the same value that is passed to the **RegisterServer** method when the nameserver is registered.

lpszAddress

A pointer to a string buffer that will contain the address of the nameserver when the function returns. This buffer should be large enough to store both IPv4 and IPv6 addresses, with a minimum length of 40 characters. If this parameter is NULL, it will be ignored.

nMaxLength

The maximum number of characters that can be copied into the string buffer. If this value is zero, the *lpszAddress* parameter will be ignored and the function will return the length of the address.

Return Value

If the method succeeds, the return value is the length of the address, not including the terminating null character. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetResolverAddress](#), [GetServerPort](#), [RegisterServer](#), [UnregisterServer](#)

CDnsClient::GetServerPort Method

```
INT GetServerPort(  
    INT nServer  
);
```

The **GetServerPort** method returns the port number registered to the specified nameserver.

Parameters

nServer

The index into the client's nameserver table. This index is the same value that is passed to the **RegisterServer** method when the nameserver is registered.

Return Value

If the method succeeds, the return value is the specified port number. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetResolverAddress](#), [GetServerAddress](#), [RegisterServer](#), [UnregisterServer](#)

CDnsClient::GetServiceName Method

```
INT GetServiceName(  
    INT nServicePort,  
    INT nServiceType,  
    LPTSTR lpszServiceName,  
    INT nMaxLength  
);  
  
INT GetServiceName(  
    INT nServicePort,  
    INT nServiceType,  
    CString& strServiceName  
);
```

The **GetServiceName** method returns the service name assigned to the specified port number.

Parameters

nServicePort

An integer which specifies the port number. This value must be a valid port number in the range of 1 through 65535.

nServiceType

An integer which specifies the protocol associated with the service. This may be one of the following values:

Value	Description
DNS_SERVICE_ANY	Match the first service entry for the specified port number regardless of the protocol used.
DNS_SERVICE_TCP	Match a service entry for the specified port number which uses the TCP protocol.
DNS_SERVICE_UDP	Match a service entry for the specified port number which uses the UDP protocol.

lpszServiceName

A pointer to a string buffer which will contain the name of the service assigned to the port number when the method returns. This parameter cannot be NULL and the buffer must be large enough to store the complete service name, including the terminating null character. An alternative version of this method accepts a **CString** object.

nMaxLength

An integer which specifies the maximum number of characters which can be copied into the string buffer.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

Port numbers can be assigned human readable service names to make them easier to reference. This method will return the name assigned to the specified port number. If the port number does not have

an assigned name, this method will return zero and the last error code will be set to ST_ERROR_INVALID_SERVICE_NAME.

Most applications should use DNS_SERVICE_ANY to return the service name assigned to a port number. Services typically use the same name and port number regardless of the protocol used to establish a connection with them. However, specifying a protocol can enable your application to determine if the service supports the protocol. For example, calling this method with port number 21 and DNS_SERVICE_UDP would result in an error because FTP only supports TCP connections.

Service names are assigned by the Internet Assigned Numbers Authority (IANA) and the database of recognized service names can be returned by calling the **GetDefaultServicesFile** method. The default location for this file is in a protected area of the Windows operating system and can only be modified by a process with administrative privileges.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::GetServicePort Method

```
INT GetServicePort(  
    LPCTSTR lpszServiceName,  
    INT nServiceType  
);
```

The **GetServicePort** method returns the port number assigned to the specified service.

Parameters

lpszServiceName

A pointer to a null terminated string which specifies the service name. Service names are not case sensitive.

nServiceType

An integer which specifies the protocol associated with the service. This may be one of the following values:

Value	Description
DNS_SERVICE_ANY	Match the first service entry for the specified port number regardless of the protocol used.
DNS_SERVICE_TCP	Match a service entry for the specified port number which uses the TCP protocol.
DNS_SERVICE_UDP	Match a service entry for the specified port number which uses the UDP protocol.

Return Value

If the method succeeds, the return value is the port number assigned to the service name. If the method fails, the return value is DNS_ERROR. To get extended error information, call **DnsGetLastError**.

Remarks

Port numbers can be assigned human readable service names to make them easier to reference. This method will return the port number assigned to the specified service name. If the service name does not exist, this method will return DNS_ERROR and the last error code will be set to ST_ERROR_INVALID_SERVICE_NAME.

Most applications should use DNS_SERVICE_ANY to return the port number assigned to a service. Services typically use the same name and port number regardless of the protocol used to establish a connection with them. However, specifying a protocol can enable your application to determine if the service supports the protocol. For example, calling this method with the service name "**ftp**" and DNS_SERVICE_UDP would result in an error because FTP only supports TCP connections.

Service names are assigned by the Internet Assigned Numbers Authority (IANA) and the database of recognized service names can be returned by calling the **GetDefaultServicesFile** method. The default location for this file is in a protected area of the Windows operating system and can only be modified by a process with administrative privileges.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnsv11.lib

CDnsClient::GetTimeout Method

```
INT GetTimeout();
```

The **GetTimeout** method returns the timeout value for the current client session.

Return Value

If the method succeeds, the return value is the timeout period. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value determines the amount of time the client will wait for a response from each query, the effective amount of time the client will wait increases with each nameserver and the total number of retries specified. For example, two nameservers registered with the client, with a default of 4 retries per nameserver and a timeout value of 10 seconds, would cause the client to wait a total of 80 seconds until it returns an error indicating that it was unable to resolve the query.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

[GetRetryCount](#), [SetRetryCount](#), [SetTimeout](#)

CDnsClient::HostNameToUnicode Method

```
INT HostNameToUnicode(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszUnicodeName,  
    INT nMaxLength  
);  
  
INT HostNameToUnicode(  
    LPCTSTR lpszHostName,  
    CString& strUnicodeName  
);
```

The **HostNameToUnicode** method converts the canonical form of a host name to its Unicode version.

Parameters

lpszHostName

Pointer to the host name as a null-terminated string. This parameter cannot be a NULL pointer or a zero length string.

lpszUnicodeName

Pointer to the string buffer that will contain the original Unicode version of the host name, including the terminating null character. It is recommended that this buffer be at least 256 characters in size. This parameter cannot be a NULL pointer. An alternate version of this method accepts a reference to a CString object.

nMaxLength

The maximum number of characters that can be copied to the *lpszUnicodeName* string buffer. This parameter cannot be zero, and must include the terminating null character.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **HostNameToUnicode** method will convert the encoded ASCII version of a host name to its Unicode version. Although any valid host name is accepted by this method, it is intended to convert a Punycode encoded host name to its original Unicode character encoding.

If the application is compiled using the Unicode character set, the value returned in *lpszUnicodeName* will be a Unicode string using UTF-16 encoding. If the ANSI character set is used, the value returned will be a Unicode string using UTF-8 encoding. To display a UTF-8 encoded host name, your application will need to convert it to UTF-16 using the **MultiByteToWideChar** function.

Although this method performs checks to ensure that the *lpszHostName* parameter is in the correct format and does not contain any illegal characters or malformed encoding, it does not validate the existence of the domain name. To check if the host name exists and has a valid IP address, use the [GetHostAddress](#) method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostAddress](#), [NormalizeHostName](#)

CDnsClient::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

See Also

[CDnsClient](#)

CDnsClient::MatchHostName Method

```
BOOL MatchHostName(  
    LPCTSTR lpszHostName,  
    LPCTSTR lpszHostMask  
    BOOL bResolve  
);
```

The **MatchHostName** method matches a host name against one or more strings that may contain wildcards.

Parameters

lpszHostName

A pointer to a string which specifies the host name or IP address to match.

lpszHostMask

A pointer to a string which specifies one or more values to match against the host name. The asterisk character can be used to match any number of characters in the host name, and the question mark can be used to match any single character. Multiple values may be specified by separating them with a semicolon.

bResolve

A boolean value which specifies if the host name or IP address should be resolved when matching the host against the mask string. If this parameter is non-zero, two checks against the host mask string will be performed; once for the host name specified and once for its IP address. If this parameter is zero, then the match is made only against the host name string provided.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **MatchHostName** method provides a convenient way for an application to determine if a given host name matches one or more mask strings which may contain wildcard characters. For example, the host name could be "www.microsoft.com" and the host mask string could be "*.microsoft.com". In this example, the method would return a non-zero value indicating the host name matched the mask. However, if the mask string was "*.net" then the method would return zero, indicating that there was no match. Multiple mask values can be combined by separating them with a semicolon; for example, the mask "*.com;*.org" would match any host name in either the .com or .org top-level domains.

If an internationalized domain name (IDN) is specified, it will be converted internally to an ASCII string using Punycode encoding. The host mask will be matched against this encoded version of the host name, not its Unicode version.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetAddress](#), [GetHostAddress](#), [GetHostName](#), [GetLocalAddress](#)

CDnsClient::NormalizeHostName Method

```
INT NormalizeHostName(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszNormalized,  
    INT nMaxLength  
);  
  
INT NormalizeHostName(  
    LPCTSTR lpszHostName,  
    CString& strNormalized  
);
```

The **NormalizeHostName** method returns the canonical form of a host name in the specified buffer.

Parameters

lpszHostName

Pointer to the host name as a null-terminated string. This parameter cannot be a NULL pointer or a zero length string.

lpszNormalized

Pointer to the string buffer that will contain the canonical form of the host name, including the terminating null character. It is recommended that this buffer be at least 256 characters in size. This parameter cannot be a NULL pointer. An alternate version of this method accepts a reference to a CString object.

nMaxLength

The maximum number of characters that can be copied to the *lpszNormalized* string buffer. This parameter cannot be zero, and must include the terminating null character.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **NormalizeHostName** method will remove all leading and trailing whitespace characters from the host name and fold all upper-case characters to lower-case. If an internationalized domain name (IDN) containing Unicode characters is passed to this method, it will be converted to an ASCII compatible format for domain names.

If the application is compiled using the Unicode character set, the host name will be converted from UTF-16 to UTF-8 and then processed. If you are unsure if an internationalized domain name will be specified as the host name, it is recommended that you use Unicode.

Although this method performs checks to ensure that the *lpszHostName* parameter is in the correct format and does not contain any illegal characters or malformed encoding, it does not validate the existence of the domain name. To check if the host name exists and has a valid IP address, use the [GetHostAddress](#) method.

It is recommended that you use this method if your application needs to store the host name, and if accepts a host name as user input. It is not necessary to call this method prior to calling the other methods that accept a host name as a parameter. They already normalize the host name and perform checks to ensure it is in the correct format.

If the *lpzHostName* parameter specifies a valid IPv4 or IPv6 address string instead of a host name, this method will return a copy of that IP address in the buffer provided by the caller. This allows the method to be used in cases where a user may input either a host name or IP address. To determine if the IP address has a corresponding host name, use the [GetHostName](#) method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdntv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::RegisterServer Method

```
INT RegisterServer(  
    INT nServer,  
    LPCTSTR lpszHostAddress,  
    INT nPort  
);
```

The **RegisterServer** method registers a nameserver with the current client session. The nameserver is used to resolve queries issued by the client, such as returning the IP address for a given host name. At least one nameserver must be registered by the client before queries are issued.

Parameters

nServer

The index into the client nameserver table. This index, starting at 0, is used to specify which slot in the client's nameserver table will be used to store the nameserver information.

lpszHostAddress

A pointer to a string that specifies the IP address of the nameserver to be registered. Note that hostnames cannot be specified.

nPort

The port number that the specified nameserver is accepting queries on. This value may be set to zero, in which case it will use the default port value.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is `DNS_ERROR`. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csdnsv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::Resolve Method

```
BOOL Resolve(  
    LPCTSTR lpszRecord,  
    LPTSTR lpszResult,  
    INT nMaxLength,  
    BOOL bHostName  
);  
  
BOOL Resolve(  
    LPCTSTR lpszRecord,  
    LPINTERNET_ADDRESS LpAddress  
);  
  
BOOL Resolve(  
    LPINTERNET_ADDRESS LpAddress,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
BOOL Resolve(  
    LPCTSTR lpszRecord,  
    CString& strResult,  
    BOOL bHostName  
);  
  
BOOL Resolve(  
    LPINTERNET_ADDRESS LpAddress,  
    CString& strHostName  
);
```

The **Resolve** method resolves the specified host name into an IP address, or an IP address into its corresponding host name.

Parameters

lpszRecord

Pointer to a string which specifies the record to be resolved. If the *bHostName* argument is non-zero, then the record is expected to be a host name; otherwise it is expected to be an IP address string in dot notation.

lpszResult

Pointer to the buffer that will contain the result of the nameserver query. If the *bHostName* argument is non-zero, then the string will contain the host's IP address in dot notation when the method returns; otherwise, it will contain the host name for the IP address specified in the *lpszRecord* argument.

nMaxLength

The maximum number of characters that can be copied into the string buffer.

bHostName

A boolean argument which determines how the record is resolved. If this value is non-zero, then the *lpszRecord* argument should specify a host name and the *lpszResult* buffer will contain the IP address for that host when the method returns. If this value is zero, then the *lpszRecord* argument should specify an IP address and the *lpszResult* buffer will contain its host name when the method returns.

lpAddress

A pointer to an `INTERNET_ADDRESS` structure which specifies the numeric form of an IPv4 or IPv6 address in network byte order. This can be used with versions of the method that resolve host names and addresses using the numeric form of the IP address instead of a string.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Resolve** method provides a convenient interface to resolve host names and IP addresses. Note that this method first looks to see if there is an entry in the local host file for the specified host name or IP address, and if one exists, it will return that record without querying the name server.

Example

```
// Create an instance of the class object
CDnsClient dnsClient;

// Resolve the address of the www.microsoft.com server
CString strHostName = _T("www.microsoft.com");
INTERNET_ADDRESS ipHostAddress;

// If the host name is resolved, then perform a reverse
// lookup on that address to obtain the actual host name
// for that server
if (dnsClient.Resolve(strHostName, &ipHostAddress))
    dnsClient.Resolve(&ipHostAddress, strHostName);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[GetAddress](#), [FormatAddress](#), [GetHostAddress](#), [GetHostFile](#), [GetHostName](#), [SetHostFile](#), [INTERNET_ADDRESS](#)

CDnsClient::SetHostFile Method

```
INT SetHostFile(  
    LPCTSTR lpszFileName  
);
```

The **SetHostFile** method specifies the name of an alternate file to use when resolving hostnames and IP addresses. The host file is used as a database that maps an IP address to one or more hostnames, and is used by the **GetHostAddress** and **GetHostName** methods. The file is a plain text file, with each line in the file specifying a record, and each field separated by spaces or tabs. The format of the file must be as follows:

```
ipaddress hostname [hostalias ...]
```

For example, one typical entry maps the name "localhost" to the local loopback IP address. This would be entered as:

```
127.0.0.1 localhost
```

The hash character (#) may be used to specify a comment in the file, and all characters after it are ignored up to the end of the line. Blank lines are ignored, as are any lines which do not follow the required format.

Parameters

lpszFileName

Pointer to a string that specifies the name of the file. If the parameter is NULL, then the current host file is cleared from the cache and only the default host file will be used to resolve hostnames and addresses.

Return Value

If the method succeeds, the return value is the number of entries in the host file. A return value of DNS_ERROR indicates failure. To get extended error information, call **GetLastError**.

Remarks

This method loads the file into memory allocated for the current thread. If the contents of the file have changed after the method has been called, those changes will not be reflected when resolving hostnames or addresses. To reload the host file from disk, call this method again with the same file name. To remove the alternate host file from memory, specify a NULL pointer as the parameter.

If a host file has been specified, it is processed before the default host file when resolving a hostname into an IP address, or an IP address into a hostname. If the host name or address is not found, or no host file has been specified, a nameserver lookup is performed.

To determine if an alternate host file has been specified, use the **GetHostFile** method. A return value of zero indicates that no alternate host file has been cached for the current thread.

A system may have a default host file, which is used to resolve hostnames before performing a nameserver lookup. To determine the name of this file, use the **GetDefaultHostFile** method. It is not necessary to specify this default host file, since it is always used to resolve host names and addresses.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the error code for the current thread. This method is typically used to clear the last error by passing a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the error code for the current thread. A value of zero clears the last error code.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or DNS_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by using the **GetLastError** method. The use of **GetLastError** is optional; an application can call the method to determine the specific reason for a method failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

CDnsClient::SetLocalDomain Method

```
INT SetLocalDomain(  
    LPCTSTR lpszDomain  
);
```

Parameters

lpszDomain

Pointer to the string which contains the local domain name. This is used as a default value when a query does not explicitly specify a domain name.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CDnsClient::SetResolverOptions Method

```
DWORD SetResolverOptions(  
    DWORD dwOptions  
);
```

The **SetResolverOptions** method changes the resolver options for the client session.

Parameters

hClient

Handle to the client session.

dwOptions

An unsigned integer that specifies one or more resolver options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
DNS_OPTION_NONE	No additional resolver options specified. This is the default value, and it is recommended that most applications do not specify additional options unless the implications of doing so are understood.
DNS_OPTION_PROMOTE	Promotes the server that successfully completed the last query to the first server that will be used to resolve subsequent queries. This option can improve performance in some cases where one or more of the registered servers are non-responsive. This option takes precedence over the DNS_OPTION_ROTATE option.
DNS_OPTION_ROTATE	Enables a round-robin selection of nameservers when performing queries. Normally each nameserver is queried in the same order. This option rotates the available nameservers so a different server is used with each query.
DNS_OPTION_AUTHONLY	Require the answer from the nameserver to be authoritative, not from the server's cache. This option is included for future expansion as most servers do not support this feature and will ignore it.
DNS_OPTION_PRIMARY	Queries are only accepted from the primary nameserver. This option is included for future expansion as most servers do not support this feature and will ignore it.
DNS_OPTION_NORECURSE	Disable the sending of recursive queries to the nameserver. Specifying this option will disable the bit in the DNS request header that specifies recursion is desired.
DNS_OPTION_NOSEARCH	Disable additional queries of higher domains in the search list if the host name cannot be resolved. If this option is specified, and the host name cannot be resolved using the local domain name an error is returned immediately. This option is ignored if no local

	domain has been specified or if the DNS_OPTION_NOSUFFIX option has been specified.
DNS_OPTION_NOSUFFIX	Disable additional queries using the local domain name if the host name is not a fully qualified domain name and cannot be resolved. This option is ignored if no local domain has been specified.
DNS_OPTION_NONAMECHECK	Disable checking the host name for invalid characters, such as the underscore and control characters. By default, host names are checked to ensure they're valid before submitting a query to the nameserver.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **SetResolverOptions** method changes the resolver options for the specified client session, modifying how nameserver queries are processed. It is recommended that most applications do not specify any resolver options and use the default behavior. Specifying these options without understanding how they can affect standard queries can result in unexpected failures. In particular, caution should be used when specifying the DNS_OPTION_NORECURSE and DNS_OPTION_NOSEARCH options as they change the normal process of resolving a host name.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[CDnsClient](#), [GetResolverOptions](#)

CDnsClient::SetRetryCount Method

```
INT SetRetryCount(  
    INT nRetries  
);
```

The **SetRetryCount** method sets the number of attempts that the client will make attempting to resolve a query. When used in conjunction with the **SetTimeout** method, it determines the total amount of time the client will spend attempting to resolve a query.

Parameters

nRetries

The number of attempts the client will make, per nameserver, to resolve a query.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The retry count determines the amount of time the client will wait for a response from each query, the effective amount of time the client will wait increases with each nameserver and the total number of retries specified. For example, two nameservers registered with the client, with a default of 4 retries per nameserver and a timeout value of 10 seconds, would cause the client to wait a total of 80 seconds until it returns an error indicating that it was unable to resolve the query.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csdnsv11.lib

[GetRetryCount](#), [GetTimeout](#), [SetTimeout](#)

CDnsClient::SetTimeout Method

```
INT SetTimeout(  
    INT nTimeout  
);
```

The **SetTimeout** method sets the number of seconds that the client will wait for a response from a nameserver. The timeout value is used each time a server in the client's nameserver table is queried. When used in conjunction with the **SetRetryCount** method, it determines the total amount of time the client will spend attempting to resolve a query.

Parameters

nTimeout

The number of seconds until the client times out waiting for a response from a nameserver.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value determines the amount of time the client will wait for a response from each query, the effective amount of time the client will wait increases with each nameserver and the total number of retries specified. For example, with two nameservers registered with the client, with a default of 4 retries per nameserver and a timeout value of 10 seconds, would cause the client to wait a total of 80 seconds until it returns an error indicating that it was unable to resolve the query.

CDnsClient::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** function in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that function for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csdnsv11.lib

CDnsClient::UnregisterServer Method

```
INT UnregisterServer(  
    INT nServer  
);
```

The **UnregisterServer** method removes the specified nameserver information from the client. Unregistering a server prevents the client from using that server to satisfy subsequent DNS queries.

Parameters

nServer

The index into the client's nameserver table. This index is the same value that is passed to the **RegisterServer** method when the nameserver is registered.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is DNS_ERROR. To get extended error information, call **GetLastError**.

Domain Name Service Data Structures

- [HOSTENT](#)
- [INTERNET_ADDRESS](#)

HOSTENT

The **HOSTENT** structure contains information about a domain name, including its IP address and any aliases which may be defined.

```
typedef struct _HOSTENT
{
    char *   h_name;
    char **  h_aliases;
    short    h_addrtype;
    short    h_length;
    char **  h_addr_list;
} HOSTENT, *LPHOSTENT;
```

Members

h_name

The fully qualified domain name (FQDN) that caused the nameserver server to return a reply.

h_aliases

A NULL-terminated array of alternate names.

h_addrtype

The type of address being returned.

h_length

The length, in bytes, of each address.

h_addr_list

A NULL-terminated list of addresses for the host. Addresses are returned in network byte order. The macro **h_addr** is defined to be **h_addr_list[0]** for compatibility with older software.

Remarks

This structure is intended to be used for backwards compatibility with legacy applications and should not be used with new applications. You cannot use this structure to obtain information for a host which is assigned an IPv6 address. Applications should use the **GetHostAddress** and **GetHostName** methods which support both IPv4 and IPv6 addresses.

The application must never attempt to modify this structure or free any of its members. There is no Unicode version of this structure, string pointers will always specify ANSI strings, even if the application is compiled to use Unicode. Only one copy of this structure is allocated per thread, so the application should copy any information it needs before calling any other methods.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: winsock2.h.

See Also

[GetHostAddress](#), [GetHostByAddress](#), [GetHostByName](#), [GetHostName](#)

INTERNET_ADDRESS

This structure represents a numeric IPv4 or IPv6 address in network byte order.

```
typedef struct _INTERNET_ADDRESS
{
    INT    ipFamily;
    BYTE   ipNumber[16];
} INTERNET_ADDRESS, *LPINTERNET_ADDRESS;
```

Members

ipFamily

An integer which identifies the type of IP address. It will be one of the following values:

Value	Description
INET_ADDRESS_UNKNOWN	The address has not been specified or the bytes in the <i>ipNumber</i> array does not represent a valid address. Functions which populate this structure will use this value to indicate that the address cannot be determined.
INET_ADDRESS_IPV4	Specifies that the address is in IPv4 format. The first four bytes of the <i>ipNumber</i> array are significant and contains the IP address. The remaining bytes are not significant and an application should not depend on them having any particular value, including zero.
INET_ADDRESS_IPV6	Specifies that the address is in IPv6 format. All bytes in the <i>ipNumber</i> array are significant. Note that it is possible for an IPv6 address to actually represent an IPv4 address. This is indicated by the first 10 bytes of the address being zero.

ipNumber

A byte array which contains the numeric form of the IP address. This array is large enough to store both IPv4 (32 bit) and IPv6 (128 bit) addresses. The values are stored in network byte order.

Remarks

The **INTERNET_ADDRESS** structure is used by some functions to represent an Internet address in a binary format that is compatible with both IPv4 and IPv6 addresses. Applications that use this structure should consider it to be opaque, and should not modify the contents of the structure directly.

For compatibility with legacy applications that expect an IP address to be 32 bits and stored in an unsigned integer, you can copy the first four bytes of the *ipNumber* array using the **CopyMemory** function or equivalent. Note that if this is done, your application should always check the *ipFamily* member first to make sure that it is actually an IPv4 address.

Requirements

Domain Name Service Constants

Value	Description
DNS_RECORD_NONE	No record type
DNS_RECORD_ADDRESS	Host address
DNS_RECORD_NS	Authoritative nameserver
DNS_RECORD_CNAME	Canonical name (alias)
DNS_RECORD_SOA	Start of Authority
DNS_RECORD_WKS	Well known services
DNS_RECORD_PTR	Domain name
DNS_RECORD_HINFO	Host information
DNS_RECORD_MINFO	Mailbox information
DNS_RECORD_MX	Mail exchange host
DNS_RECORD_TXT	Text strings
DNS_RECORD_LOC	Location information
DNS_RECORD_UINFO	User information
DNS_RECORD_UID	User ID
DNS_RECORD_GID	Group ID

SocketTools Library Error Codes

Value	Constant	Description
0x80042711	ST_ERROR_NOT_HANDLE_OWNER	Handle not owned by the current thread
0x80042712	ST_ERROR_FILE_NOT_FOUND	The specified file or directory does not exist
0x80042713	ST_ERROR_FILE_NOT_CREATED	The specified file could not be created
0x80042714	ST_ERROR_OPERATION_CANCELED	The blocking operation has been canceled
0x80042715	ST_ERROR_INVALID_FILE_TYPE	The specified file is a block or character device, not a regular file
0x80042716	ST_ERROR_INVALID_DEVICE	The specified device or address does not exist
0x80042717	ST_ERROR_TOO_MANY_PARAMETERS	The maximum number of function parameters has been exceeded
0x80042718	ST_ERROR_INVALID_FILE_NAME	The specified file name contains invalid characters or is too long
0x80042719	ST_ERROR_INVALID_FILE_HANDLE	Invalid file handle passed to function
0x8004271A	ST_ERROR_FILE_READ_FAILED	Unable to read data from the specified file
0x8004271B	ST_ERROR_FILE_WRITE_FAILED	Unable to write data to the specified file
0x8004271C	ST_ERROR_OUT_OF_MEMORY	Out of memory
0x8004271D	ST_ERROR_ACCESS_DENIED	Access denied
0x8004271E	ST_ERROR_INVALID_PARAMETER	Invalid argument passed to function
0x8004271F	ST_ERROR_CLIPBOARD_UNAVAILABLE	The system clipboard is currently unavailable
0x80042720	ST_ERROR_CLIPBOARD_EMPTY	The system clipboard is empty or does not contain any text data
0x80042721	ST_ERROR_FILE_EMPTY	The specified file does not contain any data
0x80042722	ST_ERROR_FILE_EXISTS	The specified file already exists
0x80042723	ST_ERROR_END_OF_FILE	End of file
0x80042724	ST_ERROR_DEVICE_NOT_FOUND	The specified device could not be found
0x80042725	ST_ERROR_DIRECTORY_NOT_FOUND	The specified directory could not be found
0x80042726	ST_ERROR_INVALID_BUFFER	Invalid memory address passed to function
0x80042728	ST_ERROR_NO_HANDLES	No more handles available to this process

0x80042733	ST_ERROR_OPERATION_WOULD_BLOCK	The specified operation would block the current thread
0x80042734	ST_ERROR_OPERATION_IN_PROGRESS	A blocking operation is currently in progress
0x80042735	ST_ERROR_ALREADY_IN_PROGRESS	The specified operation is already in progress
0x80042736	ST_ERROR_INVALID_HANDLE	Invalid handle passed to function
0x80042737	ST_ERROR_INVALID_ADDRESS	Invalid network address specified
0x80042738	ST_ERROR_INVALID_SIZE	Datagram is too large to fit in specified buffer
0x80042739	ST_ERROR_INVALID_PROTOCOL	Invalid network protocol specified
0x8004273A	ST_ERROR_PROTOCOL_NOT_AVAILABLE	The specified network protocol is not available
0x8004273B	ST_ERROR_PROTOCOL_NOT_SUPPORTED	The specified protocol is not supported
0x8004273C	ST_ERROR_SOCKET_NOT_SUPPORTED	The specified socket type is not supported
0x8004273D	ST_ERROR_INVALID_OPTION	The specified option is invalid
0x8004273E	ST_ERROR_PROTOCOL_FAMILY	Specified protocol family is not supported
0x8004273F	ST_ERROR_PROTOCOL_ADDRESS	The specified address is invalid for this protocol family
0x80042740	ST_ERROR_ADDRESS_IN_USE	The specified address is in use by another process
0x80042741	ST_ERROR_ADDRESS_UNAVAILABLE	The specified address cannot be assigned
0x80042742	ST_ERROR_NETWORK_UNAVAILABLE	The networking subsystem is unavailable
0x80042743	ST_ERROR_NETWORK_UNREACHABLE	The specified network is unreachable
0x80042744	ST_ERROR_NETWORK_RESET	Network dropped connection on remote reset
0x80042745	ST_ERROR_CONNECTION_ABORTED	Connection was aborted due to timeout or other failure
0x80042746	ST_ERROR_CONNECTION_RESET	Connection was reset by remote network
0x80042747	ST_ERROR_OUT_OF_BUFFERS	No buffer space is available
0x80042748	ST_ERROR_ALREADY_CONNECTED	Connection already established with remote host
0x80042749	ST_ERROR_NOT_CONNECTED	No connection established with remote host
0x8004274A	ST_ERROR_CONNECTION_SHUTDOWN	Unable to send or receive data after connection shutdown
0x8004274C	ST_ERROR_OPERATION_TIMEOUT	The specified operation has timed out
0x8004274D	ST_ERROR_CONNECTION_REFUSED	The connection has been refused by the

		remote host
0x80042750	ST_ERROR_HOST_UNAVAILABLE	The specified host is unavailable
0x80042751	ST_ERROR_HOST_UNREACHABLE	Remote host is unreachable
0x80042753	ST_ERROR_TOO_MANY_PROCESSES	Too many processes are using the networking subsystem
0x80042755	ST_ERROR_TOO_MANY_THREADS	Too many threads have been created by the current process
0x80042756	ST_ERROR_TOO_MANY_SESSIONS	Too many client sessions have been created by the current process
0x80042762	ST_ERROR_INTERNAL_FAILURE	An unexpected internal error has occurred
0x8004276B	ST_ERROR_NETWORK_NOT_READY	Network subsystem is not ready for communication
0x8004276C	ST_ERROR_INVALID_VERSION	This version of the operating system is not supported
0x8004276D	ST_ERROR_NETWORK_NOT_INITIALIZED	The networking subsystem has not been initialized
0x80042775	ST_ERROR_REMOTE_SHUTDOWN	The remote host has initiated a graceful shutdown sequence
0x80042AF9	ST_ERROR_INVALID_HOSTNAME	The specified hostname is invalid or could not be resolved
0x80042AFA	ST_ERROR_HOSTNAME_NOT_FOUND	The specified hostname could not be found
0x80042AFB	ST_ERROR_HOSTNAME_REFUSED	Unable to resolve hostname, request refused
0x80042AFC	ST_ERROR_HOSTNAME_NOT_RESOLVED	Unable to resolve hostname, no address for specified host
0x80042EE1	ST_ERROR_INVALID_LICENSE	The license for this product is invalid
0x80042EE2	ST_ERROR_PRODUCT_NOT_LICENSED	This product is not licensed to perform this operation
0x80042EE3	ST_ERROR_NOT_IMPLEMENTED	This function has not been implemented on this platform
0x80042EE4	ST_ERROR_UNKNOWN_LOCALHOST	Unable to determine local host name
0x80042EE5	ST_ERROR_INVALID_HOSTADDRESS	Invalid host address specified
0x80042EE6	ST_ERROR_INVALID_SERVICE_PORT	Invalid service port number specified
0x80042EE7	ST_ERROR_INVALID_SERVICE_NAME	Invalid or unknown service name specified
0x80042EE8	ST_ERROR_INVALID_EVENTID	Invalid event identifier specified
0x80042EE9	ST_ERROR_OPERATION_NOT_BLOCKING	No blocking operation in progress on this socket

0x80042F45	ST_ERROR_SECURITY_NOT_INITIALIZED	Unable to initialize security interface for this process
0x80042F46	ST_ERROR_SECURITY_CONTEXT	Unable to establish security context for this session
0x80042F47	ST_ERROR_SECURITY_CREDENTIALS	Unable to open client certificate store or establish client credentials
0x80042F48	ST_ERROR_SECURITY_CERTIFICATE	Unable to validate the certificate chain for this session
0x80042F49	ST_ERROR_SECURITY_DECRYPTION	Unable to decrypt data stream
0x80042F4A	ST_ERROR_SECURITY_ENCRYPTION	Unable to encrypt data stream
0x80042FA9	ST_ERROR_OPERATION_NOT_SUPPORTED	The specified operation is not supported
0x80042FAA	ST_ERROR_INVALID_PROTOCOL_VERSION	Invalid application protocol version specified
0x80042FAB	ST_ERROR_NO_SERVER_RESPONSE	No data returned from server
0x80042FAC	ST_ERROR_INVALID_SERVER_RESPONSE	Invalid data returned from server
0x80042FAD	ST_ERROR_UNEXPECTED_SERVER_RESPONSE	Unexpected response code returned from server
0x80042FAE	ST_ERROR_SERVER_TRANSACTION_FAILED	Server transaction failed
0x80042FAF	ST_ERROR_SERVICE_UNAVAILABLE	The service is currently unavailable
0x80042FB0	ST_ERROR_SERVICE_NOT_READY	The service is not ready, try again later
0x80042FB1	ST_ERROR_SERVER_RESYNC_FAILED	Unable to resynchronize with server
0x80042FB2	ST_ERROR_INVALID_PROXY_TYPE	Invalid proxy server type specified
0x80042FB3	ST_ERROR_PROXY_REQUIRED	Resource must be accessed through specified proxy
0x80042FB4	ST_ERROR_INVALID_PROXY_LOGIN	Unable to login to proxy server using specified credentials
0x80042FB5	ST_ERROR_PROXY_RESYNC_FAILED	Unable to resynchronize with proxy server
0x80042FB6	ST_ERROR_INVALID_COMMAND	Invalid command specified
0x80042FB7	ST_ERROR_INVALID_COMMAND_PARAMETER	Invalid command parameter specified
0x80042FB8	ST_ERROR_INVALID_COMMAND_SEQUENCE	Invalid command sequence specified
0x80042FB9	ST_ERROR_COMMAND_NOT_IMPLEMENTED	Specified command not implemented on this server
0x80042FBA	ST_ERROR_COMMAND_NOT_AUTHORIZED	Specified command not authorized for the current user
0x80042FBB	ST_ERROR_COMMAND_ABORTED	Specified command was aborted by the remote host
0x80042FBC	ST_ERROR_OPTION_NOT_SUPPORTED	The specified option is not supported on this server

0x80042FBD	ST_ERROR_REQUEST_NOT_COMPLETED	The current client request has not been completed
0x80042FBE	ST_ERROR_INVALID_USERNAME	The specified username is invalid
0x80042FBF	ST_ERROR_INVALID_PASSWORD	The specified password is invalid
0x80042FC0	ST_ERROR_INVALID_ACCOUNT	The specified account name is invalid
0x80042FC1	ST_ERROR_ACCOUNT_REQUIRED	Account name has not been specified
0x80042FC2	ST_ERROR_INVALID_AUTHENTICATION_TYPE	Invalid authentication protocol specified
0x80042FC3	ST_ERROR_AUTHENTICATION_REQUIRED	User authentication is required
0x80042FC4	ST_ERROR_PROXY_AUTHENTICATION_REQUIRED	Proxy authentication required
0x80042FC5	ST_ERROR_ALREADY_AUTHENTICATED	User has already been authenticated
0x80042FC6	ST_ERROR_AUTHENTICATION_FAILED	Unable to authenticate the specified user
0x80042FDB	ST_ERROR_NETWORK_ADAPTER	Unable to determine network adapter configuration
0x80042FDC	ST_ERROR_INVALID_RECORD_TYPE	Invalid record type specified
0x80042FDD	ST_ERROR_INVALID_RECORD_NAME	Invalid record name specified
0x80042FDE	ST_ERROR_INVALID_RECORD_DATA	Invalid record data specified
0x80042FDF	ST_ERROR_CONNECTION_OPEN	Data connection already established
0x80042FE0	ST_ERROR_CONNECTION_CLOSED	Server closed data connection
0x80042FE1	ST_ERROR_CONNECTION_PASSIVE	Data connection is passive
0x80042FE2	ST_ERROR_CONNECTION_FAILED	Unable to open data connection to server
0x80042FE3	ST_ERROR_INVALID_SECURITY_LEVEL	Data connection cannot be opened with this security setting
0x80042FE4	ST_ERROR_CACHED_TLS_REQUIRED	Data connection requires cached TLS session
0x80042FE5	ST_ERROR_DATA_READ_ONLY	Data connection is read-only
0x80042FE6	ST_ERROR_DATA_WRITE_ONLY	Data connection is write-only
0x80042FE7	ST_ERROR_END_OF_DATA	End of data
0x80042FE8	ST_ERROR_REMOTE_FILE_UNAVAILABLE	Remote file is unavailable
0x80042FE9	ST_ERROR_INSUFFICIENT_STORAGE	Insufficient storage on server
0x80042FEA	ST_ERROR_STORAGE_ALLOCATION	File exceeded storage allocation on server
0x80042FEB	ST_ERROR_DIRECTORY_EXISTS	The specified directory already exists
0x80042FEC	ST_ERROR_DIRECTORY_EMPTY	No files returned by the server for the specified directory
0x80042FED	ST_ERROR_END_OF_DIRECTORY	End of directory listing
0x80042FEE	ST_ERROR_UNKNOWN_DIRECTORY_FORMAT	Unknown directory format
0x80042FEF	ST_ERROR_INVALID_RESOURCE	Invalid resource name specified

0x80042FF0	ST_ERROR_RESOURCE_REDIRECTED	The specified resource has been redirected
0x80042FF1	ST_ERROR_RESOURCE_RESTRICTED	Access to this resource has been restricted
0x80042FF2	ST_ERROR_RESOURCE_NOT_MODIFIED	The specified resource has not been modified
0x80042FF3	ST_ERROR_RESOURCE_NOT_FOUND	The specified resource cannot be found
0x80042FF4	ST_ERROR_RESOURCE_CONFLICT	Request could not be completed due to the current state of the resource
0x80042FF5	ST_ERROR_RESOURCE_REMOVED	The specified resource has been permanently removed from this server
0x80042FF6	ST_ERROR_CONTENT_LENGTH_REQUIRED	Request must include the content length
0x80042FF7	ST_ERROR_REQUEST_PRECONDITION	Request could not be completed due to server precondition
0x80042FF8	ST_ERROR_UNSUPPORTED_MEDIA_TYPE	Request specified an unsupported media type
0x80042FF9	ST_ERROR_INVALID_CONTENT_RANGE	Content range specified for this resource is invalid
0x80042FFA	ST_ERROR_INVALID_MESSAGE_PART	Message is not multipart or an invalid message part was specified
0x80042FFB	ST_ERROR_INVALID_MESSAGE_HEADER	The specified message header is invalid or has not been defined
0x80042FFC	ST_ERROR_INVALID_MESSAGE_BOUNDARY	The multipart message boundary has not been defined
0x80042FFD	ST_ERROR_NO_FILE_ATTACHMENT	The current message part does not contain a file attachment
0x80042FFE	ST_ERROR_UNKNOWN_FILE_TYPE	The specified file type could not be determined
0x80042FFF	ST_ERROR_DATA_NOT_ENCODED	The specified data block could not be encoded
0x80043000	ST_ERROR_DATA_NOT_DECODED	The specified data block could not be decoded
0x80043001	ST_ERROR_FILE_NOT_ENCODED	The specified file could not be encoded
0x80043002	ST_ERROR_FILE_NOT_DECODED	The specified file could not be decoded
0x80043003	ST_ERROR_NO_MESSAGE_TEXT	No message text
0x80043004	ST_ERROR_INVALID_CHARACTER_SET	Invalid character set specified
0x80043005	ST_ERROR_INVALID_ENCODING_TYPE	Invalid encoding type specified
0x80043006	ST_ERROR_INVALID_MESSAGE_NUMBER	Invalid message number specified
0x80043007	ST_ERROR_NO_RETURN_ADDRESS	No valid return address specified

0x80043008	ST_ERROR_NO_VALID_RECIPIENTS	No valid recipients specified
0x80043009	ST_ERROR_INVALID_RECIPIENT	The specified recipient address is invalid
0x8004300A	ST_ERROR_RELAY_NOT_AUTHORIZED	The specified domain is invalid or server will not relay messages
0x8004300B	ST_ERROR_MAILBOX_UNAVAILABLE	Specified mailbox is currently unavailable
0x8004300C	ST_ERROR_MAILBOX_READONLY	The selected mailbox cannot be modified
0x8004300D	ST_ERROR_MAILBOX_NOT_SELECTED	No mailbox has been selected
0x8004300E	ST_ERROR_INVALID_MAILBOX	Specified mailbox is invalid
0x8004300F	ST_ERROR_INVALID_DOMAIN	The specified domain name is invalid or not recognized
0x80043010	ST_ERROR_INVALID_SENDER	The specified sender address is invalid or not recognized
0x80043011	ST_ERROR_MESSAGE_NOT_DELIVERED	Message not delivered to any of the specified recipients
0x80043012	ST_ERROR_END_OF_MESSAGE_DATA	No more message data available to be read
0x80043013	ST_ERROR_INVALID_MESSAGE_SIZE	The specified message size is invalid
0x80043014	ST_ERROR_MESSAGE_NOT_CREATED	The message could not be created in the specified mailbox
0x80043015	ST_ERROR_NO_MORE_MAILBOXES	No more mailboxes exist on this server
0x80043016	ST_ERROR_INVALID_EMULATION_TYPE	The specified terminal emulation type is invalid
0x80043017	ST_ERROR_INVALID_FONT_HANDLE	The specified font handle is invalid
0x80043018	ST_ERROR_INVALID_FONT_NAME	The specified font name is invalid or unavailable
0x80043019	ST_ERROR_INVALID_PACKET_SIZE	The specified packet size is invalid
0x8004301A	ST_ERROR_INVALID_PACKET_DATA	The specified packet data is invalid
0x8004301B	ST_ERROR_INVALID_PACKET_ID	The unique packet identifier is invalid
0x8004301C	ST_ERROR_PACKET_TTL_EXPIRED	The specified packet time-to-live period has expired
0x8004301D	ST_ERROR_INVALID_NEWSGROUP	Invalid newsgroup specified
0x8004301E	ST_ERROR_NO_NEWSGROUP_SELECTED	No newsgroup selected
0x8004301F	ST_ERROR_EMPTY_NEWSGROUP	No articles in specified newsgroup
0x80043020	ST_ERROR_INVALID_ARTICLE	Invalid article number specified
0x80043021	ST_ERROR_NO_ARTICLE_SELECTED	No article selected in the current newsgroup
0x80043022	ST_ERROR_FIRST_ARTICLE	First article in current newsgroup
0x80043023	ST_ERROR_LAST_ARTICLE	Last article in current newsgroup

0x80043024	ST_ERROR_ARTICLE_EXISTS	Unable to transfer article, article already exists
0x80043025	ST_ERROR_ARTICLE_REJECTED	Unable to transfer article, article rejected
0x80043026	ST_ERROR_ARTICLE_TRANSFER_FAILED	Article transfer failed
0x80043027	ST_ERROR_ARTICLE_POSTING_DENIED	Posting is not permitted on this server
0x80043028	ST_ERROR_ARTICLE_POSTING_FAILED	Posting is not permitted on this server
0x80043029	ST_ERROR_INVALID_DATE_FORMAT	The specified date format is not recognized
0x8004302A	ST_ERROR_FEATURE_NOT_SUPPORTED	The specified feature is not supported on this server
0x8004302B	ST_ERROR_INVALID_FORM_HANDLE	The specified form handle is invalid or a form has not been created
0x8004302C	ST_ERROR_INVALID_FORM_ACTION	The specified form action is invalid or has not been specified
0x8004302D	ST_ERROR_INVALID_FORM_METHOD	The specified form method is invalid or not supported
0x8004302E	ST_ERROR_INVALID_FORM_TYPE	The specified form type is invalid or not supported
0x8004302F	ST_ERROR_INVALID_FORM_FIELD	The specified form field name is invalid or does not exist
0x80043030	ST_ERROR_EMPTY_FORM	The specified form does not contain any field values
0x80043031	ST_ERROR_MAXIMUM_CONNECTIONS	The maximum number of client connections exceeded
0x80043032	ST_ERROR_THREAD_CREATION_FAILED	Unable to create a new thread for the current process
0x80043033	ST_ERROR_INVALID_THREAD_HANDLE	The specified thread handle is no longer valid
0x80043034	ST_ERROR_THREAD_TERMINATED	The specified thread has been terminated
0x80043035	ST_ERROR_THREAD_DEADLOCK	The operation would result in the current thread becoming deadlocked
0x80043036	ST_ERROR_INVALID_CLIENT_MONIKER	The specified moniker is not associated with any client session
0x80043037	ST_ERROR_CLIENT_MONIKER_EXISTS	The specified moniker has been assigned to another client session
0x80043038	ST_ERROR_SERVER_INACTIVE	The specified server is not listening for client connections
0x80043039	ST_ERROR_SERVER_SUSPENDED	The specified server is suspended and not accepting client connections
0x8004303A	ST_ERROR_NO_MESSAGE_STORE	No message store has been specified

0x8004303B	ST_ERROR_MESSAGE_STORE_CHANGED	The message store has changed since it was last accessed
0x8004303C	ST_ERROR_MESSAGE_NOT_FOUND	No message was found that matches the specified criteria
0x8004303D	ST_ERROR_MESSAGE_DELETED	The specified message has been deleted
0x8004303E	ST_ERROR_FILE_CHECKSUM_MISMATCH	The specified file checksums do not match
0x8004303F	ST_ERROR_FILE_SIZE_MISMATCH	The specified file sizes do not match
0x80043040	ST_ERROR_INVALID_FEED_URL	The news feed URL is invalid or specifies an unsupported protocol
0x80043041	ST_ERROR_INVALID_FEED_FORMAT	The internal format of the news feed is invalid
0x80043042	ST_ERROR_INVALID_FEED_VERSION	This version of the news feed is not supported
0x80043043	ST_ERROR_CHANNEL_EMPTY	There are no valid items found in this news feed
0x80043044	ST_ERROR_INVALID_ITEM_NUMBER	The specified channel item identifier is invalid
0x80043045	ST_ERROR_ITEM_NOT_FOUND	The specified channel item could not be found
0x80043046	ST_ERROR_ITEM_EMPTY	The specified channel item does not contain any data
0x80043047	ST_ERROR_INVALID_ITEM_PROPERTY	The specified item property name is invalid
0x80043048	ST_ERROR_ITEM_PROPERTY_NOT_FOUND	The specified item property has not been defined
0x80043049	ST_ERROR_INVALID_CHANNEL_TITLE	The channel title is invalid or has not been defined
0x8004304A	ST_ERROR_INVALID_CHANNEL_LINK	The channel hyperlink is invalid or has not been defined
0x8004304B	ST_ERROR_INVALID_CHANNEL_DESCRIPTION	The channel description is invalid or has not been defined
0x8004304C	ST_ERROR_INVALID_ITEM_TEXT	The description for an item is invalid or has not been defined
0x8004304D	ST_ERROR_INVALID_ITEM_LINK	The hyperlink for an item is invalid or has not been defined
0x8004304E	ST_ERROR_INVALID_SERVICE_TYPE	The specified service type is invalid
0x8004304F	ST_ERROR_SERVICE_SUSPENDED	Access to the specified service has been suspended
0x80043050	ST_ERROR_SERVICE_RESTRICTED	Access to the specified service has been

		restricted
0x80043051	ST_ERROR_INVALID_PROVIDER_NAME	The specified provider name is invalid or unknown
0x80043052	ST_ERROR_INVALID_PHONE_NUMBER	The specified phone number is invalid or not supported in this region
0x80043053	ST_ERROR_GATEWAY_NOT_FOUND	A message gateway cannot be found for the specified provider
0x80043054	ST_ERROR_MESSAGE_TOO_LONG	The message exceeds the maximum number of characters permitted
0x80043055	ST_ERROR_INVALID_PROVIDER_DATA	The request returned invalid or incomplete service provider data
0x80043056	ST_ERROR_INVALID_GATEWAY_DATA	The request returned invalid or incomplete message gateway data
0x80043057	ST_ERROR_MULTIPLE_PROVIDERS	The request has returned multiple service providers
0x80043058	ST_ERROR_PROVIDER_NOT_FOUND	The specified service provider could not be found
0x80043059	ST_ERROR_INVALID_MESSAGE_SERVICE	The specified message is not supported with this service type
0x8004305A	ST_ERROR_INVALID_MESSAGE_FORMAT	The specified message format is invalid
0x8004305B	ST_ERROR_INVALID_CONFIGURATION	The specified configuration options are invalid
0x8004305C	ST_ERROR_SERVER_ACTIVE	The requested action is not permitted while the server is active
0x8004305D	ST_ERROR_SERVER_PORT_BOUND	Unable to obtain exclusive use of the specified local port
0x8004305E	ST_ERROR_INVALID_CLIENT_SESSION	The specified client identifier is invalid for this session
0x8004305F	ST_ERROR_CLIENT_NOT_IDENTIFIED	The specified client has not provided user credentials
0x80043060	ST_ERROR_INVALID_CLIENT_STATE	The requested action cannot be performed at this time
0x80043061	ST_ERROR_INVALID_RESULT_CODE	The specified result code is not valid for this protocol
0x80043062	ST_ERROR_COMMAND_REQUIRED	The specified command is required and cannot be disabled
0x80043063	ST_ERROR_COMMAND_DISABLED	The specified command has been disabled
0x80043064	ST_ERROR_COMMAND_SEQUENCE	The command cannot be processed at this time
0x80043065	ST_ERROR_COMMAND_COMPLETED	The previous command has completed

0x80043066	ST_ERROR_INVALID_PROGRAM_NAME	The specified program name is invalid or unrecognized
0x80043067	ST_ERROR_INVALID_REQUEST_HEADER	The request header contains one or more invalid values
0x80043068	ST_ERROR_INVALID_VIRTUAL_HOST	The specified virtual host name is invalid
0x80043069	ST_ERROR_VIRTUAL_HOST_NOT_FOUND	The specified virtual host does not exist
0x8004306A	ST_ERROR_TOO_MANY_VIRTUAL_HOSTS	Too many virtual hosts created for this server
0x8004306B	ST_ERROR_INVALID_VIRTUAL_PATH	The specified virtual path name is invalid
0x8004306C	ST_ERROR_VIRTUAL_PATH_NOT_FOUND	The specified virtual path does not exist
0x8004306D	ST_ERROR_TOO_MANY_VIRTUAL_PATHS	Too many virtual paths created for this server
0x8004306E	ST_ERROR_INVALID_TASK	The asynchronous task identifier is invalid
0x8004306F	ST_ERROR_TASK_ACTIVE	The asynchronous task has not finished
0x80043070	ST_ERROR_TASK_QUEUED	The asynchronous task has been queued
0x80043071	ST_ERROR_TASK_SUSPENDED	The asynchronous task has been suspended
0x80043072	ST_ERROR_TASK_FINISHED	The asynchronous task has finished
0x80043073	ST_ERROR_INVALID_ACCOUNT_UUID	The account unique identifier is invalid
0x80043074	ST_ERROR_INVALID_ACCOUNT_ID	The application account identifier is invalid
0x80043075	ST_ERROR_INVALID_PRODUCT_ID	The product identifier identifier is invalid
0x80043076	ST_ERROR_INVALID_SERIAL_NUMBER	The product serial number is invalid
0x80043077	ST_ERROR_INVALID_APPID	The application identifier is invalid
0x80043078	ST_ERROR_INVALID_APIKEY	The application key is invalid
0x80043079	ST_ERROR_ACCOUNT_EXISTS	The application account identifier already exists
0x8004307A	ST_ERROR_ACCOUNT_NOT_CREATED	The application account identifier was not created
0x8004307B	ST_ERROR_ACCOUNT_NOT_FOUND	The application account identifier was not found
0x8004307C	ST_ERROR_ACCOUNT_NOT_EXPIRED	Access to this account has not expired
0x8004307D	ST_ERROR_ACCOUNT_NOT_UPDATED	The application account could not be updated
0x8004307E	ST_ERROR_ACCOUNT_EXPIRED	Access to this account has expired
0x8004307F	ST_ERROR_ACCOUNT_REVOKED	Access to this account has been revoked
0x80043080	ST_ERROR_APIKEY_NOT_CREATED	The application key could not be created

0x80043081	ST_ERROR_APIKEY_NOT_FOUND	The application key could not be found
0x80043082	ST_ERROR_APIKEY_NOT_EXPIRED	The application key has not expired
0x80043083	ST_ERROR_APIKEY_NOT_UNIQUE	The application key identifier is not unique
0x80043084	ST_ERROR_APIKEY_NOT_UPDATED	The application key could not be updated
0x80043085	ST_ERROR_APIKEY_NOT_DELETED	The application key could not be deleted
0x80043086	ST_ERROR_APIKEY_EXISTS	The application key already exists
0x80043087	ST_ERROR_APIKEY_EXPIRED	The application key has expired and must be refreshed
0x80043088	ST_ERROR_APIKEY_REVOKED	The application key has been revoked
0x80043089	ST_ERROR_APIKEY_APPID	The application was not found or was not specified
0x8004308A	ST_ERROR_INVALID_TOKEN	The access token is invalid or was not specified
0x8004308B	ST_ERROR_TOKEN_NOT_CREATED	The access token could not be created
0x8004308C	ST_ERROR_TOKEN_NOT_FOUND	The access token could not be found
0x8004308D	ST_ERROR_TOKEN_NOT_EXPIRED	The access token has not expired
0x8004308E	ST_ERROR_TOKEN_NOT_UPDATED	The access token was not updated
0x8004308F	ST_ERROR_TOKEN_NOT_DELETED	The access token could not be deleted
0x80043090	ST_ERROR_TOKEN_EXPIRED	The access token has expired and must be refreshed
0x80043091	ST_ERROR_TOKEN_REVOKED	The access token has been revoked
0x80043092	ST_ERROR_NO_APIKEYS_FOUND	No application keys found for this account
0x80043093	ST_ERROR_NO_TOKENS_FOUND	No access tokens found for this application key
0x80043094	ST_ERROR_NO_TOKENS_REVOKED	No access tokens have been revoked
0x80043095	ST_ERROR_INVALID_STORAGE_OBJECT	Invalid storage object identifier
0x80043096	ST_ERROR_STORAGE_OBJECT_READONLY	The storage object is read-only
0x80043097	ST_ERROR_STORAGE_OBJECT_EXPIRED	Access to the storage object has expired
0x80043098	ST_ERROR_STORAGE_OBJECT_SIZE	The storage object size exceeds storage limits
0x80043099	ST_ERROR_STORAGE_OBJECT_DIGEST	The storage object digest is invalid or cannot be computed
0x8004309A	ST_ERROR_STORAGE_OBJECT_EXISTS	A storage object with this label already exists
0x8004309B	ST_ERROR_STORAGE_OBJECT_MODIFIED	A storage object with this label has been

		modified
0x8004309C	ST_ERROR_STORAGE_OBJECT_NOT_OWNER	The current user is not the storage object owner
0x8004309D	ST_ERROR_STORAGE_OBJECT_NOT_FOUND	The specified storage object does not exist
0x8004309E	ST_ERROR_STORAGE_OBJECT_NOT_CREATED	The storage object was not created
0x8004309F	ST_ERROR_STORAGE_OBJECT_NOT_MODIFIED	The storage object was not modified
0x800430A0	ST_ERROR_STORAGE_OBJECT_NOT_RENAMED	The storage object was not renamed
0x800430A1	ST_ERROR_STORAGE_FOLDER_EMPTY	The storage folder does not contain any objects
0x800430A2	ST_ERROR_STORAGE_ACCOUNT_QUOTA	The storage account has exceeded its quota
0x800430A3	ST_ERROR_STORAGE_ACCOUNT_LIMIT	The storage account has exceeded its object limit
0x800430A4	ST_ERROR_INVALID_STORAGE_TYPE	The specified storage type is invalid
0x800430A5	ST_ERROR_INVALID_STORAGE_PROVIDER	The specified storage provider is not available
0x800430A6	ST_ERROR_INVALID_STORAGE_REGION	The specified storage region is not available
0x800430A7	ST_ERROR_INVALID_STORAGE_FOLDER	The storage folder does not exist or cannot be accessed
0x800430A8	ST_ERROR_INVALID_STORAGE_LABEL	The storage object label is invalid or undefined
0x800430A9	ST_ERROR_INVALID_QUEUE_HANDLE	The specified queue handle is invalid or the queue has been deleted
0x800430AA	ST_ERROR_INVALID_QUEUE_FILE	The specified file identifier is not valid for this queue
0x800430AB	ST_ERROR_QUEUE_RUNNING	The operation cannot be performed while the queue is running
0x800430AC	ST_ERROR_QUEUE_STOPPED	The operation cannot be performed when the queue has stopped
0x800430AD	ST_ERROR_QUEUE_EMPTY	There are no files in the specified queue
0x800430AE	ST_ERROR_QUEUE_PAUSED	The operation cannot be performed while the queue is paused
0x800430AF	ST_ERROR_QUEUE_LOCKED	The operation cannot be performed while the queue is locked
0x800430B0	ST_ERROR_FILE_NOT_QUEUED	The specified file cannot be found in the queue
0x800430B1	ST_ERROR_END_OF_QUEUE	There are no more files in the specified queue

0x800430B2	ST_ERROR_TOO_MANY_FILES	The maximum number of files have been queued for transfer
0x800430B3	ST_ERROR_NO_QUEUED_TRANSFER	No queued file transfer is currently in progress
0x800430B4	ST_ERROR_INVALID_X509_CERTIFICATE	The specified X.509 format certificate is invalid
0x800430B5	ST_ERROR_INVALID_PKCS12_CERTIFICIATE	The specified PKCS 12 format certificate is invalid
0x800430B6	ST_ERROR_INVALID_CIPHER_SUITE	The specified cipher suite is invalid or unavailable
0x800430B7	ST_ERROR_DEPRECATED_CIPHER_SUITE	The specified cipher suite is insecure and has been deprecated
0x800430B8	ST_ERROR_INVALID_CERTIFICATE_CHAIN	The certificate chain could not be validated
0x800430B9	ST_ERROR_INVALID_PRIVATE_KEY	The private key for the certificate is invalid
0x800430BA	ST_ERROR_INVALID_API_SESSION	The application session identifier is invalid
0x800430BB	ST_ERROR_EXPIRED_API_SESSION	The application session identifier has expired
0x800430BC	ST_ERROR_INVALID_API_TOKEN	The application token for this session is invalid
0x800430BD	ST_ERROR_EXPIRED_API_TOKEN	The application token for this session has expired
0x800430BE	ST_ERROR_INVALID_API_AUTHID	The authorization token for this session is invalid
0x800430BF	ST_ERROR_INVALID_API_ENDPOINT	The endpoint for the specified request is invalid
0x800430C0	ST_ERROR_INVALID_API_PAYLOAD	The data submitted with the specified request is invalid
0x800430C1	ST_ERROR_UNKNOWN_SESSION_OWNER	The current session owner is unknown or no longer valid
0x800430C2	ST_ERROR_REVOKED_SESSION_AUTH	The authorization token for this session has been revoked
0x800430C3	ST_ERROR_INVALID_URL_SCHEME	The scheme for the specified URL is invalid or not supported
0x800430C4	ST_ERROR_INVALID_URL_HOST	The host name for the specified URL is invalid
0x800430C5	ST_ERROR_INVALID_URL_PORT	The port number for the specified URL is invalid
0x800430C6	ST_ERROR_INVALID_URL_PATH	The resource path for the specified URL is invalid
0x800430C7	ST_ERROR_INVALID_CONTENT_TYPE	The content type is invalid or not

		supported
0x800430C8	ST_ERROR_UNKNOWN_CONTENT_TYPE	The content type cannot be determined
0x800430C9	ST_ERROR_INVALID_CHARSET	The specified character set is invalid or not supported
0x800430CA	ST_ERROR_INVALID_CODEPAGE	The specified ANSI code page is invalid or not supported
0x800430CB	ST_ERROR_INVALID_HEADER_TYPE	The specified header type is invalid or not supported
0x800430CC	ST_ERROR_INVALID_HEADER_NAME	The specified header name is invalid or not permitted
0x800430CD	ST_ERROR_INVALID_HEADER_VALUE	The specified header value is invalid or not permitted
0x800430CE	ST_ERROR_HEADER_NOT_FOUND	The specified header value is undefined
0x800430CF	ST_ERROR_INVALID_DIGEST_TYPE	The specified message digest type is invalid
0x800430D0	ST_ERROR_INVALID_DIGEST_VALUE	The specified message digest value is invalid
0x800430D1	ST_ERROR_FILE_DIGEST_MISMATCH	The message digest does not match the specified file
0x800430D2	ST_ERROR_FILE_CONTENT_MISMATCH	The contents of the specified files are not identical
0x800430D3	ST_ERROR_FILE_TIME_MISMATCH	The timestamps for the specified files are not identical

File Transfer Protocol Class Library

Transfer files between a local and server and perform common file management methods on the server.

Library Information

Class Name	CFtpClient
File Name	CSFTPV11.DLL
Version	11.0.2218.1855
LibID	22D6A6CD-4877-4CB9-B223-7149A9040534
Import Library	CSFTPV11.LIB
Dependencies	None
Standards	RFC 959, RFC 1579, RFC 2228

Overview

The File Transfer Protocol (FTP) library provides a comprehensive API which supports both high level operations, such as uploading or downloading files, as well as a collection of lower-level file I/O functions. In addition to file transfers, an application can create, rename and delete files and directories, search for files using wildcards and perform other common file management functions.

Files can be stored on the local file system or in memory, depending on the needs of your application and multiple file transfers be performed using a single function call. The library can also be used to manage files on the server and supports many of the common protocol extensions that can be used to access the remote file system. It understands a number of different directory listing formats, including those typically used with UNIX and Linux based systems, Windows server platforms, NetWare servers and VMS systems.

This library supports active and passive mode file transfers, firewall compatibility options, proxy servers and secure file transfers using the standard TLS 1.2 and SFTP protocols. Secure file transfers support implicit and explicit TLS sessions, client certificates and up to 256-bit AES encryption.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This class is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

File Transfer Protocol Class Methods

Class	Description
CFtpClient	Constructor which initializes the current instance of the class
~CFtpClient	Destructor which releases resources allocated by the class
Method	Description
Allocate	Allocate the specified number of bytes on the server
AttachHandle	Attach the specified client handle to this instance of the class
AttachThread	Attach the specified client handle to another thread
Cancel	Cancel the current blocking operation
ChangeDirectory	Change the current working directory on the server
ChangeDirectoryUp	Change the current working directory on the server
CloseDirectory	Close the open directory on the server
CloseFile	Close the current file on the server
Command	Send a command to the server
Connect	Establish a client connection with a server
ConnectUrl	Establish a client connection using the specified URL
CreateDirectory	Create the specified directory on the server
CreateSecurityCredentials	Create a new security credentials structure
DeleteFile	Delete a file from the server
DeleteSecurityCredentials	Delete a previously created security credentials structure
DetachHandle	Detach the handle for the current instance of this class
DisableEvents	Disable event notification
DisableTrace	Disable logging of network function calls to the trace log
Disconnect	Disconnect the client session from the server
DownloadFile	Download a file from the server to the local system
EnableEvents	Enable event notification
EnableFeature	Enable the specified feature in the client
EnableTrace	Enable logging of network function calls to a file
FreezeEvents	Suspend and resume event handling by the client
FtpEventProc	Callback function that processes events generated by the client
GetActivePorts	Return the range of local port numbers used for active transfers
GetAutoFileType	Return the file transfer type based on the file extension or content
GetBufferSize	Return the size of an internal buffer used during data transfers
GetChannelMode	Return the mode for the specified communication channel

GetClientQuota	Return quota information for the current client session
GetData	Copy the contents of a remote file to a local buffer
GetDirectory	Get the current working directory on the server
GetDirectoryFormat	Get the format which is used by the server to list files
GetErrorString	Return a description for the specified error code
GetFeatures	Return the features available to the client
GetFile	Copy a file from the server to the local system
GetFileList	Return an unparsed list of files in a string buffer
GetFileNameEncoding	Return the character encoding used when sending a file name to the server
GetFilePermissions	Return the access permissions for the specified file
GetFileSize	Return the size of a file on the server
GetFileStatus	Return file status information from the server
GetFileTime	Return the modification time for the specified file on the server
GetFileType	Return the default file type for the current session
GetFirstFile	Return the first file from the file list returned by the server
GetHandle	Return the client handle used by this instance of the class
GetLastError	Return the last error code
GetMultipleFiles	Copy multiple files from the server to the local system
GetNextFile	Return the next file from the file list returned by the server
GetPriority	Return the current priority for file transfers
GetProxyType	Return the proxy type selected by the client
GetResultCode	Return the result code from the previous command
GetResultString	Return the result string from the previous command
GetSecurityInformation	Return security information about the current client connection
GetServerInformation	Get system information about the server
GetServerStatus	Return system status of server
GetServerTimeZone	Return the timezone offset in seconds for the current server
GetServerType	Return the type of operating system the server is running on
GetStatus	Return the current client status
GetText	Download the contents of a text file to a string buffer
GetTimeout	Return the number of seconds until an operation times out
GetTransferStatus	Return file transfer statistics
IsBlocking	Determine if the current operation is blocked
IsConnected	Determine if the client is connected to the server

IsInitialized	Determine if the class has been successfully initialized
IsReadable	Determine if the client can read data from the data channel
IsWritable	Determine if the client can write data to the data channel
Login	Login to the server
Logout	Logout from the server
MountStructure	Mount a structure (filesystem) on the server
OpenDirectory	Open the specified directory for reading
OpenFile	Open the specified file for reading or writing
ProxyConnect	Establish a connection with a proxy server
PutData	Create a file on the server using the contents of a local buffer
PutFile	Copy a file from the local system to the server
PutMultipleFiles	Copy multiple files from the local system to the server
PutText	Create a text file on the server from the contents of a string buffer
Read	Read data from the server
RegisterEvent	Register an event handler for the specified event
RegisterFileType	Associate a file name extension with a specific file type
RemoveDirectory	Remove a directory from the server
RenameFile	Rename a file on the server
Reset	Reset the client connection
SetActivePorts	Set the range of local port numbers used for active transfers
SetBufferSize	Set the size of an internal buffer used during data transfers
SetChannelMode	Change the security mode for the specified channel
SetDirectoryFormat	Set the format which is used by the server to list files
SetFeatures	Set the features which can be used by the client
SetFileMode	Set the current file mode
SetFileNameEncoding	Set the character encoding type used when sending a file name to the server
SetFilePermissions	Set the access permissions for the specified file
SetFileStructure	Set the current file data structure
SetFileTime	Set the modification time for the specified file on the server
SetFileType	Set the default file type for the current session
SetLastError	Set the last error code
SetPassiveMode	Set the server in passive mode
SetPriority	Set the priority for file transfers
SetTimeout	Set the number of seconds until an operation times out
ShowError	Display a message box with a description of the specified error

UploadFile	Upload a file from the local system to the server
ValidateHostName	Validate the specified host name and return the resolved IP address
ValidateUrl	Check the contents of a string to ensure it represents a valid URL
VerifyFile	Compare the contents of a local file against a file stored on the server
Write	Write data to the server

CFtpClient::CFtpClient Method

CFtpClient();

The **CFtpClient** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **FtpInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[~CFtpClient](#), [IsInitialized](#)

CFtpClient::~CFtpClient

`~CFtpClient();`

The **CFtpClient** destructor releases resources allocated by the current instance of the **CFtpClient** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CFtpClient** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[CFtpClient](#)

CFtpClient::Allocate Method

```
INT Allocate(  
    DWORD dwFileLength,  
    DWORD dwRecSize  
);
```

The **Allocate** method instructs the server to reserve sufficient storage to accommodate the new file being transferred.

Parameters

dwFileLength

The number of bytes to allocate storage for on the server.

dwRecSize

The maximum record or page size for the file. A value of zero indicates that the file does not have a record or page structure, and the parameter is ignored.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method should be called immediately before the **OpenFile** method.

This method is ignored by those servers which do not require that the maximum size of the file be declared beforehand. The most common FTP servers running under UNIX and Windows do not require that file space be pre-allocated.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

[OpenFile](#), [SetFileMode](#), [SetFileStructure](#), [SetFileType](#)

CFtpClient::AttachHandle Method

```
VOID AttachHandle(  
    HCLIENT hClient  
);
```

The **AttachHandle** method attaches the specified client handle to the current instance of the class.

Parameters

hClient

The handle to the client session that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a client handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that client session.

If a client handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous client session from being terminated, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hClient* parameter is presumed to be a valid client handle and no checks are performed to ensure that the handle is valid. Specifying an invalid client handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[AttachThread](#), [DetachHandle](#), [GetHandle](#)

CFtpClient::AttachThread Method

```
DWORD AttachThread(  
    DWORD dwThreadId  
);
```

The **AttachThread** method attaches the specified client handle to another thread.

Parameters

dwThreadId

The ID of the thread that will become the new owner of the handle. A value of zero specifies that the current thread should become the owner of the client handle.

Return Value

If the method succeeds, the return value is the thread ID of the previous owner. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When a client handle is created, it is associated with the current thread that created it. Normally, if another thread attempts to perform an operation using that handle, an error is returned since it does not own the handle. This is used to ensure that other threads cannot interfere with an operation being performed by the owner thread. In some cases, it may be desirable for one thread in a client application to create the client handle, and then pass that handle to another worker thread. The **AttachThread** method can be used to change the ownership of the handle to the new worker thread. By preserving the return value from the method, the original owner of the handle can be restored before the worker thread terminates.

This method should be called by the new thread immediately after it has been created, and if the new thread does not release the handle itself, the ownership of the handle should be restored to the parent thread before it terminates. Under no circumstances should **AttachThread** be used to forcibly release a handle allocated by another thread while a blocking operation is in progress. To cancel an operation, use the **Cancel** method and then release the handle after the blocking method exits and control is returned to the current thread.

Note that the *dwThreadId* parameter is presumed to be a valid thread ID and no checks are performed to ensure that the thread actually exists. Specifying an invalid thread ID will orphan the client handle used by the class until the destructor is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

[AttachHandle](#), [Cancel](#), [Connect](#), [DetachHandle](#), [Disconnect](#), [GetHandle](#)

CFtpClient::Cancel Method

INT Cancel();

The **Cancel** method cancels any outstanding blocking operation in the client, causing the blocking method to fail. The application may then retry the operation or terminate the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When the **Cancel** method is called, the blocking method will not immediately fail. An internal flag is set which causes the blocking operation to exit with an error. This means that the application cannot cancel an operation and immediately perform some other operation. Instead it must allow the calling stack to unwind, returning back to the blocking operation before making any further function calls.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

[IsBlocking](#)

CFtpClient::ChangeDirectory Method

```
INT ChangeDirectory(  
    LPCTSTR lpszDirectory  
);
```

The **ChangeDirectory** method changes the current working directory for the client session.

Parameters

lpszDirectory

Points to a string that specifies the name of the directory. The file pathing and name conventions must be that of the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the CWD command to change the current working directory. The user must have the appropriate permission to access the specified directory.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[ChangeDirectoryUp](#), [CloseDirectory](#), [Command](#), [GetDirectory](#), [GetFirstFile](#), [GetNextFile](#), [GetResultCode](#), [GetResultString](#), [OpenDirectory](#)

CFtpClient::ChangeDirectoryUp Method

INT ChangeDirectoryUp();

The **ChangeDirectoryUp** method changes directory to the parent of the current working directory.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the CDUP command to the server. This command is a special case of the CWD command, and is included to simplify transferring between directory trees on those operating systems which have different syntaxes for naming the parent directory. The current user must have the appropriate permission to access the specified directory.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[ChangeDirectory](#), [Command](#), [GetDirectory](#), [GetResultCode](#), [GetResultString](#)

CFtpClient::CloseDirectory Method

INT CloseDirectory();

The **CloseDirectory** method closes the data socket connection to the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method must be called after all of the file information from the server has been returned. Because directory information is returned on the data channel, no file transfers can take place while a directory is being read.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[GetDirectoryFormat](#), [GetFileStatus](#), [GetFirstFile](#), [GetNextFile](#), [OpenDirectory](#), [SetDirectoryFormat](#)

CFtpClient::CloseFile Method

INT CloseFile();

The **CloseFile** method flushes the internal client buffers and closes the data socket connection to the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the file is opened for writing, all buffered data is written to the server before the socket is closed. This may cause the client to block until all of the data can be written. The client application should not perform any other action until the method returns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[OpenFile](#), [Read](#), [Write](#)

CFtpClient::Command Method

```
INT Command(  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszParameter  
);
```

The **Command** method sends a command to the server, and returns the result code back to the caller. This method is typically used for site-specific commands not directly supported by the API.

Parameters

lpszCommand

The command which will be executed by the server.

lpszParameter

An optional command parameter. If the command requires more than one parameter, then they should be combined into a single string, with a space separating each parameter. If the command does not accept any parameters, this value may be NULL.

Return Value

If the method succeeds, the return value is the result code returned by the server. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method should only be used when the application needs to send a custom, site-specific command or send a command that is not directly supported by this class. This method should never be used to issue a command that opens a data channel. If the application needs to transform data as it is being sent or received, and cannot use the **GetFile** or **PutFile** methods, then use the **OpenFile** method to open a data channel with the server.

By default, file names which are sent to the server using the **Command** method are sent as ANSI characters. If the Unicode version of the function is used, the file name will be converted from Unicode to ANSI using the current codepage. If the server supports UTF-8 encoded file names, the **SetFileNameEncoding** function can be used to specify that file names with non-ASCII characters should be sent as UTF-8 encoded values. It is important to note that this option is only available if the server advertises support for UTF-8 and permits that encoding type.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::Connect Method

```
BOOL Connect(  
    LPCTSTR lpszRemoteHost,  
    UINT nRemotePort,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    UINT nTimeout,  
    DWORD dwOptions  
);
```

The **Connect** method establishes a connection with the specified server.

Parameters

lpszRemoteHost

A pointer to the name of the server to connect to; this may be a fully-qualified domain name or an IP address.

nRemotePort

The port number the server is listening on. A value of zero specifies that the default port number should be used. For standard connections, the default port number is 21. For secure connections, the default port number is 990. If the secure port number is specified, an implicit TLS connection will be established by default.

lpszUserName

Points to a string that specifies the user name to be used to authenticate the current client session. If this parameter is NULL or an empty string, then the login is considered to be anonymous. Note that anonymous logins are not supported for secure connections using the SSH protocol.

lpszPassword

Points to a string that specifies the password to be used to authenticate the current client session. This parameter may be NULL or an empty string if no password is required for the specified user, or if no username has been specified.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the client should attempt to establish the data connection with the server. When the client uploads or downloads a file, normally the server establishes a second connection back to the client which is used to transfer the file data. However, if the local system is behind a firewall or a NAT router, the server may not be able to create the data connection and the transfer will fail. By specifying this option, it forces the client to establish an outbound data connection with the server. It is recommended that

	applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the client should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.
FTP_OPTION_NOAUTH	This option specifies the server does not require authentication, or that it requires an alternate authentication method. When this option is used, the client connection is flagged as authenticated as soon as the connection to the server has been established. Note that using this option to bypass authentication may result in subsequent errors when attempting to retrieve a directory listing or transfer a file. It is recommended that you consult the technical reference documentation for the server to determine its specific authentication requirements.
FTP_OPTION_KEEPAIVE	This option specifies the client should attempt to keep the connection with the server active for an extended period of time. It is important to note that regardless of this option, the server may still choose to disconnect client sessions that are holding the command channel open but are not performing file transfers.
FTP_OPTION_NOAUTHRSA	This option specifies that RSA authentication should not be used with SSH-1 connections. This option is ignored with SSH-2 connections and should only be specified if required by the server. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_NOPWDNUL	This option specifies the user password cannot be terminated with a null character. This option is ignored with SSH-2 connections and should only be specified if required by the server. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_NOREKEY	This option specifies the client should never attempt a repeat key exchange with the server. Some SSH servers do not support rekeying the session, and this can cause the client to become non-responsive or abort the connection after being connected for an hour. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_COMPATSID	This compatibility option changes how the session ID is handled during public key authentication with older SSH servers. This option should only be specified when

	connecting to servers that use OpenSSH 2.2.0 or earlier versions. This option has no effect on standard or secure connections using SSL.
FTP_OPTION_COMPATHMAC	This compatibility option changes how the HMAC authentication codes are generated. This option should only be specified when connecting to servers that use OpenSSH 2.2.0 or earlier versions. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_VIRTUALHOST	This option specifies the server supports virtual hosting, where multiple domains are hosted by a server using the same external IP address. If this option is enabled, the client will send the HOST command to the server upon establishing a connection.
FTP_OPTION_VERIFY	This option specifies that file transfers should be automatically verified after the transfer has completed. If the server supports the XMD5 command, the transfer will be verified by calculating an MD5 hash of the file contents. If the server does not support the XMD5 command, but does support the XCRC command, the transfer will be verified by calculating a CRC32 checksum of the file contents. If neither the XMD5 or XCRC commands are supported, the transfer is verified by comparing the size of the file. Automatic file verification is only performed for binary mode transfers because of the end-of-line conversion that may occur when text files are uploaded or downloaded.
FTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
FTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. This option is the same as specifying FTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.
FTP_OPTION_SECURE_IMPLICIT	This option specifies the client should attempt to immediately establish secure TLS connection with the server. This option is typically used when connecting to a server on port 990, which is the default port number used for FTPS.
FTP_OPTION_SECURE_EXPLICIT	This option specifies the client should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure connection. This option is typically used when connecting to the server on ports other than 990.

FTP_OPTION_SECURE_SHELL	This option specifies the client should use the Secure Shell (SSH) protocol to establish the connection. This option will automatically be selected if the connection is established using port 22, the default port for SSH.
FTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
FTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established. This option also forces all connections to be outbound and enables the firewall compatibility features in the client.
FTP_OPTION_KEEPALIVE_DATA	This option specifies the client should attempt to keep the control connection active during a file transfer. Normally, when a data transfer is in progress, no additional commands are issued on the control channel until the transfer completes. Specifying this option automatically enables the FTP_OPTION_KEEPALIVE option and forces the client to continue to issue NOOP commands during the file transfer. This option only applies to FTP and FTPS connections and has no effect on connections using SFTP (SSH).
FTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
FTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the handle is synchronized across multiple threads.
FTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller files being uploaded or downloaded using fast network connections.
FTP_OPTION_TLS_REUSE	This option specifies that TLS session reuse should be

	enabled for secure connections. This option is only supported on Windows 8.1 or Windows Server 2012 R2 and later platforms, and it should only be used when explicitly required by the server. This option is not compatible with servers built using OpenSSL 1.0.2 and earlier versions which do not provide Extended Master Secret (EMS) support as outlined in RFC7627.
--	----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Return Value

If the method succeeds, the return value is a non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **Connect** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

If the `FTP_OPTION_KEEPALIVE` option is specified, a background worker thread will be created to monitor the command channel and periodically send NOOP commands to the server if no commands have been sent recently. This can prevent the server from terminating the client connection during idle periods where no commands are being issued. However, it is important to keep in mind that many servers can be configured to also limit the total amount of time a client can be connected to the server, as well as the amount of time permitted between file transfers. If the server does not respond to the NOOP command, this option will be automatically disabled for the remainder of the client session.

If the `FTP_OPTION_SECURE_EXPLICIT` option is specified, the client will establish a standard connection to the server and send the AUTH TLS command to the server. If the server does not accept this command, it will then send the AUTH SSL command. If both commands are rejected by the server, an explicit TLS session cannot be established. By default, both the command and data channels will be encrypted when a secure connection is established. To change this, use the **SetChannelMode** method.

The *dwOptions* argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the `FTP_OPTION_FREETHREAD` option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

Example

```
// Connect to a server using a standard (non-secure) connection on  
// the default port. The username and password are not encrypted.
```

```
bResult = ftpClient.Connect(lpszRemoteHost,  
                             FTP_PORT_DEFAULT,
```

```

        lpszUserName,
        lpszPassword,
        FTP_TIMEOUT,
        FTP_OPTION_DEFAULT);

// Connect to a server using the default port and then initiate a
// secure connection using the AUTH TLS command

bResult = ftpClient.Connect(lpszRemoteHost,
                            FTP_PORT_DEFAULT,
                            lpszUserName,
                            lpszPassword,
                            FTP_TIMEOUT,
                            FTP_OPTION_PASSIVE | FTP_OPTION_SECURE_EXPLICIT);

// Connect to a server on port 990 and immediately initiate a
// secure connection as soon as the connection is established

bResult = ftpClient.Connect(lpszRemoteHost,
                            FTP_PORT_SECURE,
                            lpszUserName,
                            lpszPassword,
                            FTP_TIMEOUT,
                            FTP_OPTION_PASSIVE | FTP_OPTION_SECURE_IMPLICIT);

// Connect to a server on port 22 using the Secure Shell (SFTP)
// protocol to transfer files

bResult = ftpClient.Connect(lpszRemoteHost,
                            FTP_PORT_SSH,
                            lpszUserName,
                            lpszPassword,
                            FTP_TIMEOUT,
                            FTP_OPTION_SECURE_SHELL);

```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[ConnectUrl](#), [CreateSecurityCredentials](#), [Disconnect](#), [GetSecurityInformation](#), [ProxyConnect](#), [SetChannelMode](#)

CFtpClient::ConnectUrl Method

```
BOOL ConnectUrl(  
    LPCTSTR lpszUrl,  
    UINT nTimeout,  
    DWORD dwOptions  
);
```

The **ConnectUrl** method establishes a connection with the specified server using a URL.

Parameters

lpszUrl

A pointer to a string which specifies the URL for the server. The URL must follow the conventions for the File Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the client should attempt to establish the data connection with the server. When the client uploads or downloads a file, normally the server establishes a second connection back to the client which is used to transfer the file data. However, if the local system is behind a firewall or a NAT router, the server may not be able to create the data connection and the transfer will fail. By specifying this option, it forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the client should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.
FTP_OPTION_NOAUTH	This option specifies the server does not require authentication, or that it requires an alternate authentication method. When this option is used, the client connection is flagged as authenticated as soon as the connection to the server has been established. Note

	that using this option to bypass authentication may result in subsequent errors when attempting to retrieve a directory listing or transfer a file. It is recommended that you consult the technical reference documentation for the server to determine its specific authentication requirements.
FTP_OPTION_KEEPAIVE	This option specifies the client should attempt to keep the connection with the server active for an extended period of time. It is important to note that regardless of this option, the server may still choose to disconnect client sessions that are holding the command channel open but are not performing file transfers.
FTP_OPTION_NOAUTHRSA	This option specifies that RSA authentication should not be used with SSH-1 connections. This option is ignored with SSH-2 connections and should only be specified if required by the server. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_NOPWDNUL	This option specifies the user password cannot be terminated with a null character. This option is ignored with SSH-2 connections and should only be specified if required by the server. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_NOREKEY	This option specifies the client should never attempt a repeat key exchange with the server. Some SSH servers do not support rekeying the session, and this can cause the client to become non-responsive or abort the connection after being connected for an hour. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_COMPATSID	This compatibility option changes how the session ID is handled during public key authentication with older SSH servers. This option should only be specified when connecting to servers that use OpenSSH 2.2.0 or earlier versions. This option has no effect on standard or secure connections using SSL.
FTP_OPTION_COMPATHMAC	This compatibility option changes how the HMAC authentication codes are generated. This option should only be specified when connecting to servers that use OpenSSH 2.2.0 or earlier versions. This option has no effect on standard or secure connections using TLS.
FTP_OPTION_VIRTUALHOST	This option specifies the server supports virtual hosting, where multiple domains are hosted by a server using the same external IP address. If this option is enabled, the client will send the HOST command to the server upon establishing a connection.
FTP_OPTION_VERIFY	This option specifies that file transfers should be

	<p>automatically verified after the transfer has completed. If the server supports the XMD5 command, the transfer will be verified by calculating an MD5 hash of the file contents. If the server does not support the XMD5 command, but does support the XCRC command, the transfer will be verified by calculating a CRC32 checksum of the file contents. If neither the XMD5 or XCRC commands are supported, the transfer is verified by comparing the size of the file. Automatic file verification is only performed for binary mode transfers because of the end-of-line conversion that may occur when text files are uploaded or downloaded.</p>
FTP_OPTION_TRUSTEDSITE	<p>This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.</p>
FTP_OPTION_SECURE	<p>This option specifies the client should attempt to establish a secure connection with the server. This option is the same as specifying FTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.</p>
FTP_OPTION_SECURE_IMPLICIT	<p>This option specifies the client should attempt to immediately establish secure TLS connection with the server. This option is typically used when connecting to a server on port 990, which is the default port number used for FTPS.</p>
FTP_OPTION_SECURE_EXPLICIT	<p>This option specifies the client should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure connection. This option is typically used when connecting to the server on ports other than 990.</p>
FTP_OPTION_SECURE_SHELL	<p>This option specifies the client should use the Secure Shell (SSH) protocol to establish the connection. This option will automatically be selected if the connection is established using port 22, the default port for SSH.</p>
FTP_OPTION_SECURE_FALLBACK	<p>This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.</p>
FTP_OPTION_TUNNEL	<p>This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is</p>

	established. This option also forces all connections to be outbound and enables the firewall compatibility features in the client.
FTP_OPTION_KEEPALIVE_DATA	This option specifies the client should attempt to keep the control connection active during a file transfer. Normally, when a data transfer is in progress, no additional commands are issued on the control channel until the transfer completes. Specifying this option automatically enables the FTP_OPTION_KEEPALIVE option and forces the client to continue to issue NOOP commands during the file transfer. This option only applies to FTP and FTPS connections and has no effect on connections using SFTP (SSH).
FTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
FTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the handle is synchronized across multiple threads.
FTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller files being uploaded or downloaded using fast network connections.
FTP_OPTION_TLS_REUSE	This option specifies that TLS session reuse should be enabled for secure connections. This option is only supported on Windows 8.1 or Windows Server 2012 R2 and later platforms, and it should only be used when explicitly required by the server. This option is not compatible with servers built using OpenSSL 1.0.2 and earlier versions which do not provide Extended Master Secret (EMS) support as outlined in RFC7627.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **ConnectUrl** method is a high-level method that uses an FTP URL to establish a connection with a server. Unlike the other connection related methods such as **Connect**, this method does more than simply connect to the server. It will also authenticate the client session, change the current working

directory and set the default file transfer mode. By default, this method will always place the client in passive mode, ensuring the broadest compatibility with most servers. The **ValidateUrl** method can be used to verify that a URL is valid prior to calling this function.

The URL must be complete, and specify either a standard or secure FTP scheme:

```
[ftp|ftps|sftp]://[username : password] @ hostname [:port] / [path / ...]  
[filename]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. If a path is specified as part of the URL, the method will attempt to change the current working directory. The paths in an FTP URL are relative to the home directory of the user account and are not absolute paths starting at the root directory on the server. If a file name is also specified in the URL, it will be ignored and only the file path will be used. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "ftp" scheme is used and the FTP_OPTION_SECURE option is specified, that option will be ignored. To establish a secure connection, either the "ftps" or "sftp" scheme must be specified.

The **ConnectUrl** method is designed to provide a simpler, more convenient interface to establishing a connection with a server. However, complex connections such as those using a proxy server or a secure connection which uses a client certificate will require the program to use the lower-level connection methods. If you only need to upload or download a file using a URL, then refer to the **UploadFile** and **DownloadFile** methods.

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **ConnectUrl** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

The *dwOptions* argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the FTP_OPTION_FREETHREAD option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

Example

```
CFTPClient ftpClient;  
  
if (!ftpClient.ConnectUrl(_T("ftp://ftp.sockettools.com/")))  
{  
    ftpClient.ShowError();  
    return;  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpClient::CreateDirectory Method

```
INT CreateDirectory(  
    LPCTSTR lpszDirectory  
);
```

The **CreateDirectory** method creates the specified directory on the server.

Parameters

lpszDirectory

Points to a string that specifies the name of the directory. The file pathing and name conventions must be that of the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the MKD command to create the directory. The user must have the appropriate permission to create the specified directory.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpClient::CreateSecurityCredentials Method

```
BOOL CreateSecurityCredentials(  
    DWORD dwProtocol,  
    DWORD dwOptions,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName  
);  
  
BOOL CreateSecurityCredentials(  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName  
);  
  
BOOL CreateSecurityCredentials(  
    LPCTSTR lpszCertName  
);
```

The **CreateSecurityCredentials** method establishes the security credentials for the client session.

Parameters

dwProtocol

A bitmask of supported security protocols. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows

	Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.
SECURITY_PROTOCOL_SSH2	The Secure Shell 2.0 protocol should be used when establishing the connection. This is the default version of the protocol that is supported by most SSH servers.

dwOptions

A value which specifies one or more options. This value should always be zero for connections using SSH. This member is constructed by using a bitwise operator with any of the following values:

Value	Description
CREDENTIAL_STORE_CURRENT_USER	The library will attempt to open a store for the current user using the certificate store name provided in this structure. If no options are specified, then this is the default behavior.
CREDENTIAL_STORE_LOCAL_MACHINE	The library will attempt to open a local machine store using the certificate store name provided in this structure. If this option is specified, the library will always search for a local machine store before searching for the store by that name for the current user.
CREDENTIAL_STORE_FILENAME	The certificate store name is a file that contains the certificate and private key that will be used.

lpzUserName

A pointer to a string which specifies the certificate owner's username. A value of NULL specifies that no username is required. Currently this parameter is not used and any value specified will be ignored.

lpzPassword

A pointer to a string which specifies the certificate owner's password. A value of NULL specifies that no password is required. This parameter is only used if a PKCS #12 (PFX) certificate file is specified and that certificate has been secured with a password. This value will be ignored the current user or

local machine certificate store is specified.

lpszCertStore

A pointer to a string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The method will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the method will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the method will return an error indicating that the certificate could not be found.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

A client application only needs to call this method if the server requires that the client provide a certificate as part of the process of negotiating the secure session. If a certificate is required, note that it must have a private key associated with it. Attempting to use a certificate that does not have a private key will result in an error during the connection process indicating that the client credentials could not be established.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user, or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *dwOptions* parameter should be set to CREDENTIAL_STORE_FILENAME and the *lpszCertStore*

parameter should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. If a password was specified when the certificate was created, it must be provided in the *lpzPassword* parameter or the library will be unable to access the certificate.

Note that the *lpzUserName* and *lpzPassword* parameters are optional values which are used to access the certificate store or client certificate. They are not the credentials which are used when establishing the connection with the remote host or authenticating the client session. In most cases, these parameters can be NULL or omitted.

Example

```
pClient->CreateSecurityCredentials(  
    SECURITY_PROTOCOL_DEFAULT,  
    0,  
    NULL,  
    NULL,  
    lpzCertStore,  
    lpzCertName);  
  
bConnected = pClient->Connect(lpzHostName,  
    FTP_PORT_SECURE,  
    FTP_TIMEOUT,  
    FTP_OPTION_SECURE);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[Connect](#), [DeleteSecurityCredentials](#), [GetSecurityInformation](#), [SECURITYCREDENTIALS](#)

CFtpClient::DeleteFile Method

```
INT DeleteFile(  
    LPCTSTR lpszFileName  
);
```

The **DeleteFile** method deletes the specified file from the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file to delete. The file pathing and name conventions must be that of the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The current user must have the appropriate permission to delete the file, or an error will be returned by the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFile](#), [PutFile](#), [RenameFile](#)

CFtpClient::DeleteSecurityCredentials Method

VOID DeleteSecurityCredentials();

The **DeleteSecurityCredentials** method releases the security credentials for the current session.

Parameters

None.

Return Value

None.

Remarks

This method can be used to release the memory allocated to the client or server credentials after a secure connection has been terminated. The security credentials are released when the class destructor is called, so it is normally not required that the application explicitly call this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CreateSecurityCredentials](#)

CFtpClient::DetachHandle Method

HCLIENT DetachHandle();

The **DetachHandle** method detaches the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to detach a client handle created by the class for use with the SocketTools API. Once the client handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CFtpClient::DisableEvents Method

INT DisableEvents();

The **DisableEvents** method disables the event notification mechanism, preventing subsequent event notification messages from being posted to the application's message queue.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **DisableEvents** method is used to disable event message posting for the specified client session. Although this will immediately prevent any new events from being generated, it is possible that messages could be waiting in the message queue. Therefore, an application must be prepared to handle client event messages after this method has been called.

This method is automatically called if the client has event notification enabled, and the **Disconnect** method is called. The same issues regarding outstanding event messages also applies in this situation, requiring that the application handle event messages that may reference a client handle that is no longer valid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

See Also

[EnableEvents](#), [RegisterEvent](#)

CFtpClient::DisableTrace Method

BOOL DisableTrace();

The **DisableTrace** method disables the logging of socket function calls to the trace log.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, a value of zero is returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[EnableTrace](#)

CFtpClient::Disconnect Method

VOID Disconnect();

The **Disconnect** method terminates the connection with the server, closing the socket and releasing the memory allocated for the client session.

Parameters

None.

Return Value

None.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

[Connect](#), [ProxyConnect](#)

CFtpClient::DownloadFile Method

```
BOOL DownloadFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    UINT nTimeout  
    DWORD dwOptions  
    LPFTPTRANSFERSTATUS lpStatus  
    FTPEVENTPROC lpEventProc  
    DWORD_PTR dwParam  
);
```

The **DownloadFile** method downloads the specified file from the server to the local system.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be created, overwritten or appended to. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the complete URL of the file to be downloaded. The URL must follow the conventions for the File Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response before failing the operation. A value of zero specifies that the default timeout period of sixty seconds will be used.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the client should attempt to establish the data connection with the server. When the client uploads or downloads a file, normally the server establishes a second connection back to the client which is used to transfer the file data. However, if the local system is behind a firewall or a NAT router, the server may not be able to create the data connection and the transfer will fail. By specifying this option, it forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the client should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data

	transfers.
FTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol.
FTP_OPTION_SECURE_EXPLICIT	This option specifies the client should use the AUTH command to negotiate an explicit secure connection. Some servers may only require this when connecting to the server on ports other than 990.

lpStatus

A pointer to an FTPTRANSFERSTATUS structure which contains information about the status of the current file transfer. If this information is not required, a NULL pointer may be specified as the parameter.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **FtpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **DownloadFile** method provides a convenient way for an application to download a file in a single method call. Based on the connection information specified in the URL, it will connect to the server, authenticate the session, change the current working directory if necessary and then download the file to the local system. The URL must be complete, and specify either a standard or secure FTP scheme:

```
[ftp|ftps|sftp]://[username : password] @ hostname [:port] / [path / ...]
[filename] [;type=a|i]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. If a path is specified as part of the URL, the method will attempt to change the current working directory. Note that the path in an FTP URL is relative to the home directory of the user account and is not an absolute path starting at the root directory on the server. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "ftp" scheme is used and the FTP_OPTION_SECURE option is specified, that option will be ignored. To establish a secure connection, either the "ftps" or "sftp" scheme must be specified.

The optional "type" value at the end of the file name determines if the file should be downloaded as a text or binary file. A value of "a" specifies that the file should be downloaded as a text file. A value of "i" specifies that the file should be downloaded as a binary file. If the type is not explicitly specified, the file will be downloaded as a binary file.

The *lpStatus* parameter can be used by the application to determine the final status of the transfer, including the total number of bytes copied, the amount of time elapsed and other information related to the transfer process. If this information isn't needed, then this parameter may be specified as NULL.

The ***lpEventProc*** parameter specifies a pointer to a function which will be periodically called during the file transfer process. This can be used to check the status of the transfer by calling **GetTransferStatus** and then update the program's user interface. For example, the callback function could calculate the percentage for how much of the file has been transferred and then update a progress bar control. The ***dwParam*** parameter is used in conjunction with the event handler and specifies a user-defined value that is passed to the callback function. One common use in a C++ program is to pass the ***this*** pointer as the value, and then cast it back to an object pointer inside the callback function. If no event handler is required, then a NULL pointer can be specified as the value for ***lpEventProc*** and the ***dwParam*** parameter will be ignored.

The **DownloadFile** method is designed to provide a simpler interface for downloading a file. However, complex connections such as those using a proxy server or a secure connection which uses a client certificate will require the program to establish the connection using **Connect** and then use **GetFile** to download the file.

Example

```
CFTPClient ftpClient;
CString strLocalFile = _T("c:\\temp\\database.mdb");
CString strFileURL = _T("ftp://ftp.example.com/updates/database.mdb");

// Download the file using the specified URL
if (!ftpClient.DownloadFile(strLocalFile, strFileURL))
{
    ftpClient.ShowError();
    return;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpClient::EnableEvents Method

```
INT EnableEvents(  
    HWND hEventWnd,  
    UINT uEventMsg  
);
```

The **EnableEvents** method enables event notifications using Windows messages.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Applications should use the **RegisterEvent** method to register an event handler which is invoked when an event occurs.

Parameters

hEventWnd

Handle to the window which will receive the client notification messages. This parameter must specify a valid window handle. If a NULL handle is specified, event notification will be disabled.

uEventMsg

The message that is received when a client event occurs. This value must be greater than 1024.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **EnableEvents** method is used to request that notification messages be posted to the specified window whenever a client event occurs. This allows an application to monitor the status of different client operations, such as a file transfer.

The *wParam* argument will contain the client handle, the low word of the *lParam* argument will contain the event ID, and the high word will contain any error code. If no error has occurred, the high word will always have a value of zero. The following events may be generated:

Value	Description
FTP_EVENT_CONNECT	The control connection to the server has completed. The high word of the <i>lParam</i> parameter should be checked, since this notification message will be posted if an error has occurred.
FTP_EVENT_DISCONNECT	The server has closed the control connection to the client. The client should read any remaining data and disconnect.
FTP_EVENT_OPENFILE	The data connection to the server has completed. The high word of the <i>lParam</i> parameter should be checked, since this notification message will be posted if an error has occurred.
FTP_EVENT_CLOSEFILE	The server has closed the data connection to the client. The client should read any remaining data and close the data channel.
FTP_EVENT_READFILE	Data is available to read by the calling process. No additional messages will be posted until the client has read at least some of the data. This

	event is only generated if the client is in asynchronous mode.
FTP_EVENT_WRITEFILE	The client can now write data. This notification is sent after a connection has been established, or after a previous attempt to write data has failed because it would result in a blocking operation. This event is only generated if the client is in asynchronous mode.
FTP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
FTP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.
FTP_EVENT_COMMAND	A command has been issued by the client and the server response has been received and processed. This event can be used to log the result codes and messages returned by the server in response to actions taken by the client.
FTP_EVENT_PROGRESS	The client is in the process of sending or receiving a file on the data channel. This event is called periodically during a transfer so that the client can update any user interface components such as a status control or progress bar.
FTP_EVENT_GETFILE	This event is generated when a file download has completed. If multiple files are being downloaded, this event will be generated for each file.
FTP_EVENT_PUTFILE	This event is generated when a file upload has completed. If multiple files are being uploaded, this event will be generated for each file.

It is not required that the client be placed in asynchronous mode in order to receive command and progress event notifications. To disable event notification, call the **DisableEvents** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpClient::EnableFeature Method

```
BOOL EnableFeature(  
    DWORD dwFeature,  
    BOOL bEnable  
);
```

The **EnableFeature** method enables or disables a specific server feature available to the client.

Parameters

dwFeature

An unsigned integer which specifies the feature to be enabled to disabled for the current client session. Refer to the documentation for the **GetFeatures** method for a list of available features.

bEnabled

A boolean flag which specifies if the feature should be enabled or disabled. If the value is non-zero, the library will attempt to use that feature on the server. If the value is zero, the feature is disabled. If an application calls a method which requires a specific feature and that feature is disabled, the method will fail with an error indicating the feature is not supported.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return a value of zero. To get extended error information, call the **GetLastError** method.

Remarks

The **EnableFeature** method is used to enable or disable a specific feature for the current session. When a client connection is first established, features are enabled based on the server type and the server's response to the FEAT command. However, as the client issues commands to the server, if the server reports that the command is unrecognized that feature will automatically be disabled in the client. An application can use the **EnableFeature** method to control what commands will be sent to the server, or re-enable a command that was previously disabled.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

CFtpClient::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of socket function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the server.

Trace method logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpClient::EnumFiles Method

```
INT EnumFiles(  
    LPCTSTR lpszDirectory,  
    LPCTSTR lpszFileMask,  
    DWORD dwOptions,  
    LPFTPFILESTATUSEX lpFileList,  
    INT nMaxFiles  
);
```

The **EnumFiles** method populates an array of structures that contain information about the files in a directory.

Parameters

lpszDirectory

A pointer to a string that specifies the name of a directory on the server. If this parameter is NULL or points to an empty string, the method will return the files in the current working directory. This string cannot contain wildcard characters and must specify a valid directory name that exists on the server.

lpszFileMask

A pointer to a string that specifies a wildcard file mask that is used to return a subset of files in the directory. If this parameter is NULL or an empty string then all of the files in the directory will be returned.

dwOptions

An unsigned integer value that specifies one or more options. This parameter can be a combination of one or more of the following values:

Value	Description
FTP_ENUM_DEFAULT	The method will return both regular files and subdirectories.
FTP_ENUM_FILE	The method will return only regular files.
FTP_ENUM_DIRECTORY	The method will return only subdirectories.
FTP_ENUM_FULLPATH	The method will return the full path of the file or subdirectory.

lpFileList

A pointer to an array of [FTPFILESTATUSEX](#) structures which contains information about each of the files in the specified directory. This parameter cannot be NULL, and the array must be large enough to store the number of files specified by the *nMaxFiles* parameter.

nMaxFiles

An integer value that specifies the maximum number of files that should be returned. This value must be greater than zero and the *lpFileList* parameter must provide an array that is large enough to store information about each file.

Return Value

If the method succeeds, the return value is the number of files returned by the method. If the directory is empty or there are no files that match the specified wildcard file mask, the method will return zero. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **EnumFiles** method provides a high-level interface for obtaining a list of available files in a directory on the server in a single function call. This is an alternative to opening a directory and returning information about each file by calling the **GetNextFile** method in a loop.

This method temporarily changes the current working directory to the directory specified by the *lpszDirectory* parameter. The current working directory will be restored to its original value when the method returns. The user must have the appropriate permissions to access the directory or this method will fail.

To obtain information on a subset of files in the directory, you can specify a wildcard file mask. For FTP and FTPS (SSL) sessions, this value is passed as a parameter to the LIST command and the server performs the wildcard matching. For SFTP (SSH) sessions the wildcard matching is performed by the library, and the standard conventions for Windows file wildcards are used.

By default, the *szFileName* member for each **FTPFILESTATUSEX** structure will contain the base file name. If the FTP_ENUM_FULLPATH option is specified, the method will return the full path name to the file. The library must be able to automatically determine the path delimiter that is used by the server. This is done by examining how the server identifies itself, the current directory format and the path the server returns for the current working directory. For example, UNIX based servers use the forward slash as a path delimiter. If the method cannot determine what the appropriate path delimiter is, it will ignore this option and return only the base file name.

This method will cause the current thread to block until the file listing completes, a timeout occurs or the operation is canceled.

Example

```
LPFTPFILESTATUSEX lpFileList = new FTPFILESTATUSEX[MAXFILECOUNT];

// Return all of the regular files in the current working directory
INT nResult = pClient->EnumFiles(FTP_ENUM_FILE, lpFileList, MAXFILECOUNT);

if (nResult == FTP_ERROR)
{
    DWORD dwError = pClient->GetLastError();
    _tprintf(_T("EnumFiles failed, error 0x%08lx\n"), dwError);
    return;
}

_tprintf(_T("EnumFiles returned %d files\n"), nResult);
for (INT nIndex = 0; nIndex < nResult; nIndex++)
{
    _tprintf(_T("file=\"%s\" size=%I64d\n"), lpFileList[nIndex].szFileName,
        lpFileList[nIndex].uiFileSize);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpClient::FreezeEvents Method

```
INT FreezeEvents(  
    BOOL bFreeze  
);
```

The **FreezeEvents** method is used to suspend and resume event handling by the client.

Parameters

bFreeze

A non-zero value specifies that event handling should be suspended by the client. A zero value specifies that event handling should be resumed.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method should be used when the application does not want to process events, such as when a modal dialog is being displayed. When events are suspended, all client events are queued. If events are re-enabled at a later point, those queued events will be sent to the application for processing. Note that only one of each event will be generated. For example, if the client has suspended event handling, and four read events occur, once event handling is resumed only one of those read events will be posted to the client. This prevents the application from being flooded by a potentially large number of queued events.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

CFtpClient::GetActivePorts Method

```
INT GetActivePorts(  
    UINT *lpnLowPort,  
    UINT *lpnHighPort  
);
```

The **GetActivePorts** method returns the local port numbers used for active mode file transfers.

Parameters

lpnLowPort

Points to an unsigned integer that will contain the low port number when the function returns.

lpnHighPort

Points to an unsigned integer that will contain the high port number when the function returns.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method is used to determine the default port numbers being used for active mode file transfers. When using active mode, the client listens for an inbound connection from the server rather than establishing an outbound connection for the data transfer. In most cases, passive mode transfers are preferred because they mitigate potential compatibility issues with firewalls and NAT routers.

If active mode transfers are required, the default port range used when listening for the server connection is between 1024 and 5000. This is the standard range of ephemeral ports used by the Windows operating system. However, under some circumstances that range of ports may be too small, or a firewall may be configured to deny inbound connections on ephemeral ports. In that case, the **SetActivePorts** method can be used to specify a different range of port numbers.

While it is technically permissible to assign the low and high port numbers to the same value, effectively specifying a single active port number, this is not recommended as it can cause the transfer to fail unexpectedly if multiple file transfers are performed. A minimum range of at least 1000 ports is recommended. For example, if you specify a low port value of 40000 then it is recommended that the high port value be at least 41000. The maximum port value is 65535.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[SetActivePorts](#), [SetPassiveMode](#)

GetAutoFileType Method

```
UINT GetAutoFileType(  
    LPCTSTR lpszFileName,  
    BOOL bScanFile  
);
```

The **GetAutoFileType** method returns the file transfer type based on the file extension or content.

Parameters

lpszFileName

A pointer to a null-terminated string which specifies the local path to the file. This parameter cannot be NULL and cannot specify a local device name or directory.

bScanFile

An optional value which specifies if the contents of the file should be scanned. A value of zero indicates that only the file extension should be used to determine the file type, while a non-zero value specifies the contents of the file should be examined if the file type cannot be determined based on its extension. This parameter value is zero (false) by default.

Return Value

If the method succeeds, the return value is the file transfer type. If the method fails, the return value is `INVALID_FILE_TYPE`. To get extended error information, call **GetLastError**.

Remarks

This method is used to determine the file transfer type to be used when uploading or downloading files. This method is called internally when `FILE_TYPE_AUTO` is specified as the default file type. The return value may be one of the following:

Value	Description
<code>FILE_TYPE_ASCII</code>	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
<code>FILE_TYPE_EBCDIC</code>	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server. Not all servers support this file type. It is recommended that you only specify this type if you know that it is required by the server to transfer data correctly.
<code>FILE_TYPE_IMAGE</code>	The file is a binary file and no data conversion of any type is performed on the file. This is the default file type for most data files and executable programs. If the type of file cannot be automatically determined, it will always be considered a binary file. If this file type is specified when uploading or downloading text files, the native end-of-line character sequences will be preserved.

If the file extension or contents are not recognized, the default file transfer type for the client session will be returned. This will usually be `FILE_TYPE_IMAGE`, however this can be changed by calling the **RegisterFileType** method. The file type for the current client session can be explicitly set using the

SetFileType method.

If the **bScanFile** parameter is non-zero, the local file will be opened in a shared reading mode and up to 4,096 bytes will be examined to determine if it contains binary data. If the file is currently locked or has been opened exclusively by another process, the file type associated with the file extension will be returned instead. Text files which contain UTF-16 text will always return a file type of FILE_TYPE_IMAGE because they can contain non-ASCII characters and/or embedded null characters.

If the **bScanFile** parameter is non-zero and the file type cannot be determined based on the file name extension, the file specified by **lpzFileName** must exist and be a regular file. If the file does not exist, an error will be returned and the last error code will be set to ST_ERROR_FILE_NOT_FOUND. If the **bScanFile** parameter is zero, no errors will be returned if the file does not exist, the function will only check the file name extension to determine the file type. When downloading a file, the **bScanFile** parameter should normally be zero because the local file may not exist yet.

CFtpClient::GetBufferSize Method

```
INT GetBufferSize();
```

The **GetBufferSize** method returns the size in bytes of an internal buffer that will be used during data transfers.

Parameters

None.

Return Value

If the method succeeds, the return value is the size of the internal buffer that will be used in data transfers. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The speed of data transfers, particularly on uploads, may be sensitive to network type and configuration, and the size of the internal buffer used for data transfers. The default size of this buffer will result in good performance for a wide range of network characteristics. A larger buffer will not necessarily result in better performance. For example, a value of 1460, which is the typical Maximum Transmission Unit (MTU), may be optimal in many situations.

CFtpClient::GetChannelMode Method

```
INT GetChannelMode(  
    INT nChannel  
);
```

The **GetChannelMode** method returns the mode of the specified communications channel.

Parameters

nChannel

An integer value which specifies which channel to return information for. It may be one of the following values:

Value	Description
FTP_CHANNEL_COMMAND	Return information about the command channel. This is the communication channel used to send commands to the server and receive command result and status information from the server.
FTP_CHANNEL_DATA	Return information about the data channel. This is the communication channel used to send or receive data during a file transfer.

Return Value

If the method succeeds, the return value is the mode for the specified channel. If the method fails, it will return FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetChannelMode** method returns a integer which may be one of the following values:

Value	Description
FTP_CHANNEL_CLEAR	The channel is not encrypted. This is the default mode for both channels when a standard, non-secure connection is established with the server.
FTP_CHANNEL_SECURE	The channel is encrypted. This is the default mode for both channels when a secure connection is established with the server.

CFtpClient::GetClientQuota Method

```
INT GetClientQuota(  
    LPFTPCLIENTQUOTA lpClientQuota  
);
```

The **GetClientQuota** method returns information about file quotas for the current client session.

Parameters

lpClientQuota

A pointer to an [FTPCLIENTQUOTA](#) structure which contains the quota information returned by the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the XQUOTA command to obtain information for the current client session. If the server does not support this command, the method will fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

CFtpClient::GetData Method

```
INT GetData(  
    LPCTSTR lpszRemoteFile,  
    LPBYTE lpBuffer,  
    LPDWORD lpdwLength  
);  
  
INT GetData(  
    LPCTSTR lpszRemoteFile,  
    HGLOBAL *lpBuffer,  
    LPDWORD lpdwLength  
);  
  
INT GetData(  
    LPCTSTR lpszRemoteFile,  
    LPTSTR lpBuffer,  
    DWORD dwMaxLength  
);  
  
INT GetData(  
    LPCTSTR lpszRemoteFile,  
    CString& strBuffer  
);
```

The **GetData** method transfers the contents of a file on the server to the specified buffer.

Parameters

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be transferred to the local system. The file naming conventions must be that of the host operating system.

lpBuffer

A pointer to a buffer which will contain the data transferred from the server. In alternate forms of the method, this argument may also be a pointer to a global memory handle or reference a **CString** object.

lpdwLength

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpBuffer* parameter. If the *lpBuffer* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the actual length of the file that was downloaded.

dwMaxLength

An unsigned integer value which specifies the maximum number of characters can be copied into the *lpBuffer* string. This parameter is used with the version of the method that returns the data in a character array and includes the terminating null character. This value must be greater than one and the *lpBuffer* parameter cannot be NULL, otherwise the method will return an error.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetData** method is used to download the contents of a remote file into a local buffer. The

method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the contents of the file. In this case, the *lpBuffer* parameter will point to the buffer that was allocated, the value that the *lpdwLength* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpBuffer* parameter point to a global memory handle which will contain the file data when the method returns. In this case, the value that the *lpdwLength* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

If the third method or fourth method is used, where the data is returned in a string buffer, the data may be modified so that the end-of-line character sequence matches the convention used by the Windows platform (a carriage return character followed by a linefeed). If Unicode is being used, the data will be converted from a byte array to a Unicode string. An application should only use these versions of the **GetData** method if the remote file contains text.

It is important for your application to initialize the value of the *lpdwLength* parameter correctly. This parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when downloading the file, the variable passed to this method may have a value of zero when the method returns, indicating no data has been returned to the caller.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hgb1Buffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Return the file data into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hgb1Buffer parameter
nResult = pClient->GetData(lpszRemoteFile, &hgb1Buffer, &cbBuffer);

if (nResult != FTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // contents of the file data
    lpBuffer = (LPBYTE)GlobalLock(hgb1Buffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hgb1Buffer);
    GlobalFree(hgb1Buffer);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::GetDirectory Method

```
INT GetDirectory(  
    LPTSTR lpszDirectory,  
    INT cbDirectory  
);
```

The **GetDirectory** method copies the current working directory on the server to the specified buffer.

Parameters

lpszDirectory

Points to a buffer that will contain the name of the current working directory on the server. The file pathing and name conventions must be that of the server.

cbDirectory

The maximum number of characters that may be copied into the buffer, including the terminating null-character.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the PWD command to the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ChangeDirectory](#), [CreateDirectory](#), [RemoveDirectory](#)

CFtpClient::GetDirectoryFormat Method

INT GetDirectoryFormat();

The **GetDirectoryFormat** method returns an identifier which specifies what format is being used by the server to list files. By default, the library will automatically determine the appropriate format, but this value may be overridden by the **SetDirectoryFormat** method.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Refer to the **SetDirectoryFormat** method for a list of directory format types that are supported by the library. This method can be used to determine which format was selected by the library after a file listing has been retrieved.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

CFtpClient::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT cbDescription  
);  
  
INT GetErrorString(  
    DWORD dwErrorCode,  
    CString& strDescription  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length. An alternate form of the method accepts a **CString** variable which will contain the error description.

cbDescription

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is zero, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLastError](#), [SetLastError](#), [ShowError](#)

CFtpClient::GetFeatures Method

DWORD GetFeatures();

The **GetFeatures** method returns the server features available to the client.

Parameters

None.

Return Value

If the method succeeds, the return value is one or more bit flags which specify the features that are available to the client. If the method fails, it will return zero. Because it is possible that no features would be enabled, a return value of zero does not always indicate an error. An application should call **GetLastError** to determine if an error code has been set.

Remarks

The **GetFeatures** method returns a value which may be a combination of one or more of the following bit flags:

Value	Description
FTP_FEATURE_SIZE	The server supports the SIZE command to determine the size of a file. If this feature is not enabled, the library will attempt to use the MLST or STAT command to determine the file size.
FTP_FEATURE_STAT	The server supports using the STAT command to return information about a specific file. If this feature is not enabled, the client may not be able to obtain information about a specific file such as its size, permissions or modification time.
FTP_FEATURE_MDTM	The server supports the MDTM command to obtain information about the modification time for a specific file. This command may also be used to set the file time on the server.
FTP_FEATURE_REST	The server supports restarting file transfers using the REST command. If this feature is not enabled, the client will not be able to restart file transfers and must upload or download the complete file.
FTP_FEATURE_SITE	The server supports site specific commands using the SITE command. If this feature is not enabled, no site specific commands will be sent to the server.
FTP_FEATURE_IDLE	The server supports setting the idle timeout period using the SITE IDLE command to specify the number of seconds that the client may idle before the server terminates the connection.
FTP_FEATURE_CHMOD	The server supports modifying the permissions of a specific file using the SITE CHMOD command. If this feature is not enabled, the client will not be able to set the permissions for a file.
FTP_FEATURE_AUTH	The server supports explicit TLS sessions using the AUTH command. If this feature is not enabled, the client will only be able to connect to a secure server that uses implicit TLS connections. Changing this feature has no effect on standard,

	non-secure connections.
FTP_FEATURE_PBSZ	The server supports the PBSZ command which specifies the buffer size used with secure data connections. If this feature is disabled, it may prevent the client from changing the protection level on the data channel. Changing this feature has no effect on standard, non-secure connections.
FTP_FEATURE_PROT	The server supports the PROT command which specifies the protection level for the data channel. If this feature is disabled, the client will be unable to change the protection level on the data channel. Changing this feature has no effect on standard, non-secure connections.
FTP_FEATURE_CCC	The server supports the CCC command which returns the command channel to a non-secure mode. Changing this feature has no effect on standard, non-secure connections.
FTP_FEATURE_HOST	The server supports the HOST command which enables a client to specify the hostname after establishing a connection with a server that supports virtual hosting.
FTP_FEATURE_MLST	The server supports the MLST command which returns status information for files. If this feature is enabled, the MLST command will be used instead of the STAT command.
FTP_FEATURE_MFMT	The server supports the MFMT command which is used to change the last modification time for a file. If this command is supported, it is used instead of the MDTM command to change the modification time for a file.
FTP_FEATURE_XCRC	The server supports the XCRC command which returns the CRC-32 checksum for the contents of a specified file. This command is used for file verification.
FTP_FEATURE_XMD5	The server supports the XMD5 command which returns an MD5 hash for the contents of a specified file. This command is used for file verification.
FTP_FEATURE_LANG	The server supports the LANG command which sets the language used for the current client session. Command responses and file naming conventions will use the specified language.
FTP_FEATURE_UTF8	The server supports the OPTS UTF-8 command which specifies UTF-8 encoding when specifying filenames. This feature is typically used in conjunction with setting the default language for the client session.
FTP_FEATURE_XQUOTA	The server supports the XQUOTA command which returns quota information for the current client session.
FTP_FEATURE_UTIME	The server supports the UTIME command which is used to change the last modification time for a specified file.

When a client connection is first established, features are enabled based on the server type and the server's response to the FEAT command. However, as the client issues commands to the server, if the

server reports that the command is unrecognized that feature will automatically be disabled in the client.

For example, the first time an application calls the **GetFileSize** method to determine the size of a file, the library will try to use the SIZE command. If the server reports that the SIZE command is not available, that feature will be disabled and the library will not use the command again during the session unless it is explicitly re-enabled. This is designed to prevent the library from repeatedly sending invalid commands to a server, which may result in the server aborting the connection.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[EnableFeature](#), [SetFeatures](#)

CFtpClient::GetFile Method

```
INT GetFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions  
    DWORD dwOffset  
);
```

The **GetFile** method transfers the specified file on the server to the local system.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be created, overwritten or appended to. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be transferred to the local system. The file naming conventions must be that of the host operating system.

dwOptions

An unsigned integer that specifies one or more options. This parameter may be any one of the following values:

Value	Description
FTP_TRANSFER_DEFAULT	This option specifies the default transfer mode should be used. If the local file exists, it will be overwritten with the contents of the downloaded file.
FTP_TRANSFER_APPEND	This option specifies that if the local file exists, the contents of file on the server is appended to the local file. If the local file does not exist, it is created.

dwOffset

A byte offset which specifies where the file transfer should begin. The default value of zero specifies that the file transfer should start at the beginning of the file. A value greater than zero is typically used to restart a transfer that has not completed successfully. Note that specifying a non-zero offset requires that the server support the REST command to restart transfers.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ChangeDirectory](#), [EnableEvents](#), [GetMultipleFiles](#), [GetTransferStatus](#), [PutFile](#), [PutMultipleFiles](#), [RegisterEvent](#), [SetBufferSize](#), [VerifyFile](#)

CFtpClient::GetFileList Method

```
INT GetFileList(
    LPCTSTR lpszDirectory,
    DWORD dwOptions,
    LPTSTR lpszBuffer,
    INT nMaxLength
);

INT GetFileList(
    LPCTSTR lpszDirectory,
    DWORD dwOptions,
    CString& strBuffer
);
```

The **GetFileList** method returns an unparsed list of files in the specified directory.

Parameters

lpszDirectory

A pointer to a string that specifies the name of a directory and/or a wildcard file mask. The format of the directory name must match the file naming conventions of the server. If this parameter is NULL or points to an empty string, the current working directory will be used.

dwOptions

An unsigned integer that specifies one or more options. This parameter may be any one of the following values:

Value	Description
FTP_LIST_DEFAULT	This option specifies the server should return a complete listing of files in the specified directory with as much detail as possible. This typically means that the file size, date, ownership and access rights will be returned to the client. Information about the files are returned in lines of text, with each line terminated by carriage return and linefeed (CRLF) characters. The exact format of the data returned is specific to the server operating system.
FTP_LIST_NAMEONLY	This option specifies the server should only return a list of file names, with no additional information about the file. Each file name is terminated by carriage return and linefeed (CRLF) characters.

lpszBuffer

A pointer to a string buffer that will contain the list of files when the function returns. This buffer should be large enough to store the complete file listing and a terminating null character. If the buffer is smaller than the total amount of data returned by the server, the data will be truncated. This parameter cannot be NULL.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character.

Return Value

If the function succeeds, the return value is the number of bytes copied into the string buffer, not

including the terminating null character. If the function fails, the return value is `FTP_ERROR`. To get extended error information, call **FtpGetLastError**.

Remarks

The **GetFileList** method returns a list of files in the specified directory, copying the data to a string buffer. Unlike the other methods like **EnumFiles** that parse a directory listing and return information in an **FTPFILESTATUS** structure, this method returns the unparsed file list data. The actual format of the data that is returned depends on the operating system and how the server implements file listings. For example, UNIX servers typically return the output from the **/bin/ls** command.

Some servers may not support file listings for any directory other than the current working directory. If an error is returned when specifying a directory name, try changing the current working directory using the **ChangeDirectory** method and then call this method again, passing `NULL` or an empty string as the *lpzDirectory* parameter.

This method can be particularly useful when the client is connected to a server that returns file listings in a format that is not recognized by the library. The application can retrieve the unparsed file listing from the server and parse the contents. Note that if you specify the `FTP_LIST_NAMEONLY` option, the data will only contain a list of file names and there will be no way for the application to know if they represent a regular file or a subdirectory.

This method is supported for both FTP and SFTP (SSH) connections, however the format of the data may differ depending on which protocol is used. Most UNIX based FTP servers will not list files and subdirectories that begin with a period, however most SFTP servers will return a list of all files, even those that begin with a period.

This function will cause the current thread to block until the file listing completes, a timeout occurs or the operation is canceled.

Example

```
CString strFileList;

nResult = pClient->GetFileList(NULL, FTP_LIST_DEFAULT, strFileList);

if (nResult != FTP_ERROR)
    pEditCtl1->SetWindowText(strFileList);
else
{
    pClient->ShowError();
    return;
}
```

Requirements

CFtpClient::GetFileNameEncoding Method

INT GetFileNameEncoding();

The **GetFileNameEncoding** method returns an identifier which specifies what type of encoding is being used when file names are sent to the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the type of encoding that is used. If the method fails, the return value is FTP_ERROR. To get extended error information, call **FtpGetLastError**.

Remarks

Refer to the **SetFileNameEncoding** method for a list of encoding types that are supported by the library.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

CFtpClient::GetFilePermissions Method

```
INT GetFilePermissions(  
    LPCTSTR lpszFileName,  
    LPDWORD lpdwPermissions  
);
```

The **GetFilePermissions** method returns information about the access permissions for a specific file on the server.

Parameters

lpszFileName

A pointer to a string which contains the name of the file that the access permissions are to be returned for. The filename cannot contain any wildcard characters.

lpdwPermissions

A pointer to an unsigned integer which will contain the access permissions for the file when the method returns. The file permissions are represented as bit flags, and may be one or more of the following values:

Value	Description
FILE_OWNER_READ	The owner has permission to open the file for reading. If the current user is the owner of the file, this grants the user the right to download the file to the local system.
FILE_OWNER_WRITE	The owner has permission to open the file for writing. If the current user is the owner of the file, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_OWNER_EXECUTE	The owner has permission to execute the contents of the file. The file is typically either a binary executable, script or batch file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_GROUP_READ	Users in the specified group have permission to open the file for reading. If the current user is in the same group as the file owner, this grants the user the right to download the file.
FILE_GROUP_WRITE	Users in the specified group have permission to open the file for writing. On some platforms, this may also imply permission to delete the file. If the current user is in the same group as the file owner, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_GROUP_EXECUTE	Users in the specified group have permission to execute the contents of the file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_WORLD_READ	All users have permission to open the file for reading. This permission grants any user the right to download the file to the local system.

FILE_WORLD_WRITE	All users have permission to open the file for writing. This permission grants any user the right to replace the file. If this permission is set for a directory, this grants any user the right to create and delete files.
FILE_WORLD_EXECUTE	All users have permission to execute the contents of the file. If this permission is set for a directory, this may also grant all users the right to open that directory and search for files in that directory.

Return Value

If the method succeeds, the return value is a result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the STAT command to retrieve information about the specified file. On some systems, the STAT command will not return information on files that contain spaces or tabs in the filename. In this case, the method will fail and value pointed to by the *lpdwPermissions* parameter will be zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFileStatus](#), [SetFilePermissions](#)

CFtpClient::GetFileSize Method

```
INT GetFileSize(  
    LPCTSTR lpszFileName,  
    LPDWORD lpFileSize  
);  
  
INT GetFileSize(  
    LPCTSTR lpszFileName,  
    ULARGE_INTEGER *lpFileSize  
);
```

The **GetFileSize** method returns the size of the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file.

lpFileSize

Points to an unsigned integer that will contain the size of the specified file in bytes. For files larger than 4GiB, this parameter should point to an unsigned 64-bit integer.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the SIZE command to determine the length of the specified file. Not all servers implement this command, in which case the method call will fail, and the *lpFileSize* parameter will be set to zero.

Note that if the file on the server is a text file, it is possible that the value returned by this method will not match the size of the file when it is downloaded to the local system. This is because different operating systems use different sequences of characters to mark the end of a line of text, and when a file is transferred in text mode, the end of line character sequence is automatically converted to a carriage return-linefeed, which is the convention used by the Windows platform.

Some FTP servers will refuse to return the size of a file if the current file type is set to FILE_TYPE_ASCII because the size of a text file on the server may not accurately reflect what the size of the file will be on the local system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFileStatus](#), [OpenDirectory](#)

CFtpClient::GetFileStatus Method

```
BOOL GetFileStatus(  
    LPCTSTR lpszFileName,  
    LPFTPFILESTATUS lpFileStatus  
);
```

The **GetFileStatus** method returns information about a specific file on the server.

Parameters

lpszFileName

A pointer to a string which contains the name of the file that status information will be returned on. The file name cannot contain any wildcard characters.

lpFileStatus

A pointer to an [FTPFILESTATUS](#) structure which contains information about the file returned by the server.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method uses the STAT command to retrieve information about the specified file. Unlike the **GetFirstFile** and **GetNextFile** methods, which read through a file list returned on the data channel, this method reads the result of a command string. For applications that need information about a specific file, using this method can be considerably faster than iterating through all of the files in a given directory. Note that not all servers support using the command in this way.

On some systems, the STAT command will not return information on files that contain spaces or tabs in the filename. In this case, the FTPFILESTATUS structure members will be empty strings and zero values.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::GetFileTime Method

```
INT GetFileTime(  
    LPCTSTR lpszFileName,  
    LPSYSTEMTIME lpFileTime,  
    BOOL bLocalize  
);
```

The **GetFileTime** method returns the modification time for the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file.

lpFileTime

Points to a [SYSTEMTIME](#) structure that will be set to the current modification time for the remote file.

bLocalize

A boolean flag which specifies if the file time is localized to the current timezone. If this value is non-zero, then the file time is adjusted to that the time is local to the current system. If this value is zero, the file time is returned in UTC time.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetFileTime** method can be used to determine the date and time that a file was last modified on the server. The time may either be localized to the current system, or it may be returned as UTC time. If you plan on changing the values returned in the SYSTEMTIME structure and then calling **SetFileTime** method to modify the file time on the server, you should do not localize the time.

This method uses the MDTM command to determine the modification time of the specified file. If the server does not support this command, the method will attempt to use the STAT command to determine the file modification time.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFileStatus](#), [OpenDirectory](#), [SetFileTime](#)

CFtpClient::GetFileType Method

UINT GetFileType();

The **GetFileType** method returns the default file type for the current client session.

Parameters

None.

Return Value

If the method succeeds, the return value is an integer value that identifies the current file type. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **GetFileType** method will return one of the following values:

Value	Description
<code>FILE_TYPE_AUTO</code>	The file type should be automatically determined based on the file name extension. If the file extension is unknown, the file type should be determined based on the contents of the file. The library has an internal list of common text file extensions, and additional file extensions can be registered using the RegisterFileType method.
<code>FILE_TYPE_ASCII</code>	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
<code>FILE_TYPE_EBCDIC</code>	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server.
<code>FILE_TYPE_IMAGE</code>	The file is a binary file and no data conversion of any type is performed on the file. This is the default file type for most data files and executables. If the type of file cannot be automatically determined, it will always be considered a binary file.

If this method is called when connected to an SFTP (SSH) server, the default file type will always be `FILE_TYPE_IMAGE` because SFTP does not differentiate between text files and binary files.

The **SetFileType** function can be used to change the default file type. To determine the automatic file type for a specific file based on its extension or contents, use the **GetAutoFileType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

See Also

[GetAutoFileType](#), [OpenFile](#), [RegisterFileType](#), [SetFileMode](#), [SetFileStructure](#), [SetFileType](#), [SetPassiveMode](#)

CFtpClient::GetFirstFile Method

```
BOOL GetFirstFile(  
    LPFTPFILESTATUS lpFileStatus  
);
```

The **GetFirstFile** method returns the first file in the directory listing returned by the server after a call to the **OpenDirectory** method.

Parameters

lpFileStatus

A pointer to an [FTPFILESTATUS](#) structure which contains information about the file returned by the server.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This file list information returned by the server is cached by the library, allowing you to use this method to reposition back to the beginning of the file list.

Example

```
if (pClient->OpenDirectory() != FTP_ERROR)  
{  
    FTPFILESTATUS ftpFile;  
    BOOL bResult;  
  
    bResult = pClient->GetFirstFile(&ftpFile);  
    while (bResult)  
    {  
        // The ftpFile structure contains information about the file  
        bResult = pClient->GetNextFile(&ftpFile);  
    }  
  
    pClient->CloseDirectory();  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::GetHandle Method

```
HCLIENT GetHandle();
```

The **GetHandle** method returns the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value INVALID_CLIENT will be returned.

Remarks

This method is used to obtain the client handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[AttachHandle](#), [DetachHandle](#), [IsInitialized](#)

CFtpClient::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or FTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[GetErrorString](#), [SetLastError](#), [ShowError](#)

CFtpClient::GetMultipleFiles Method

```
INT GetMultipleFiles(  
    LPCTSTR lpszLocalDirectory,  
    LPCTSTR lpszRemoteDirectory,  
    LPCTSTR lpszFileMask  
);
```

The **GetMultipleFiles** method copies one or more files from the server to the local host, using the specified wildcard.

Parameters

lpszLocalDirectory

Pointer to a string which specifies the local directory where the files will be copied to. A NULL pointer or empty string specifies that files should be copied to the current working directory.

lpszRemoteDirectory

Pointer to a string which specifies the remote directory where the files will be copied from. A NULL pointer or empty string specifies that the files should be copied from the current working directory on the server.

lpszFileMask

Pointer to a string which specifies the files that are to be copied from the server to the local system. The file mask should follow the native conventions used for wildcard file matches on the server.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetMultipleFiles** method is used to transfer files from the server to the local host which match a specified wildcard file mask. This method requires that the client be able to automatically list and parse directory listings from the server, otherwise an error will be returned. All files will be transferred using the current file type as specified by the **SetFileType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::GetNextFile Method

```
BOOL GetNextFile(  
    LPFTPFILESTATUS lpFileStatus  
);
```

The **GetNextFile** method returns the next file in the directory listing returned by the server.

Parameters

lpFileStatus

A pointer to an [FTPFILESTATUS](#) structure which contains information about the file returned by the server.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **GetNextFile** method returns the next file in the directory listing. If the last file has been returned, the method will return zero and the client should call the **CloseDirectory** method to close the directory.

Example

```
if (pClient->OpenDirectory() != FTP_ERROR)  
{  
    FTPFILESTATUS ftpFile;  
    BOOL bResult;  
  
    bResult = pClient->GetFirstFile(&ftpFile);  
    while (bResult)  
    {  
        // The ftpFile structure contains information about the file  
        bResult = pClient->GetNextFile(&ftpFile);  
    }  
  
    pClient->CloseDirectory();  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::GetPriority Method

```
INT GetPriority();
```

The **GetPriority** method returns a value which specifies the priority of file transfers.

Parameters

None.

Return Value

If the method succeeds, the return value is the current file transfer priority. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetPriority** method can be used to determine the current priority assigned to file transfers performed by the client. It may be one of the following values:

Value	Description
FTP_PRIORITY_NORMAL	The default priority which balances resource utilization and transfer speed. It is recommended that most applications use this priority.
FTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the transfer. It is typically used with worker threads running in the background when the amount of time required perform the transfer is not critical.
FTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the transfer and meters the bandwidth allocated for the transfer. This priority will increase the average amount of time required to complete a file transfer.
FTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the transfer, allocating more memory for internal buffering. It can be used when it is important to transfer the file quickly, and there are no other threads currently performing file transfers at the time.
FTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization while attempting to transfer the file as quickly as possible. If the file transfer is being performed in the main UI thread, this priority can cause the application to appear to become non-responsive. No events will be generated during the transfer.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[SetPriority](#)

CFtpClient::GetProxyType Method

INT GetProxyType();

The **GetProxyType** method returns the type of proxy that the client is connected to. By default, no proxy server is specified and this method returns a value of FTP_PROXY_NONE. For a list of possible proxy server types, refer to the **ProxyConnect** method.

Parameters

None.

Return Value

If the method succeeds, the return value identifies the type of proxy that the client is connected to. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Connect](#), [ProxyConnect](#)

CFtpClient::GetResultCode Method

```
INT GetResultCode();
```

The **GetResultCode** method reads the result code returned by the server in response to a command. The result code is a three-digit numeric code, and indicates if the operation succeeded, failed or requires additional action by the client.

Parameters

None.

Return Value

If the method succeeds, the return value is the result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Result codes are three-digit numeric values returned by the server. They may be broken down into the following ranges:

Value	Description
100-199	Positive preliminary result. This indicates that the requested action is being initiated, and the client should expect another reply from the server before proceeding.
200-299	Positive completion result. This indicates that the server has successfully completed the requested action.
300-399	Positive intermediate result. This indicates that the requested action cannot complete until additional information is provided to the server.
400-499	Transient negative completion result. This indicates that the requested action did not take place, but the error condition is temporary and may be attempted again.
500-599	Permanent negative completion result. This indicates that the requested action did not take place.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** cstdlib11.h
- Import Library:** csftpv11.lib

See Also

[Command](#), [GetResultString](#)

CFtpClient::GetResultString Method

```
INT GetResultString(  
    LPTSTR lpszResult,  
    INT cbResult  
);  
  
INT GetResultString(  
    CString& strResult  
);
```

The **GetResultString** method returns the last message sent by the server along with the result code.

Parameters

lpszResult

A pointer to the buffer that will contain the result string returned by the server. An alternate form of the method accepts a **CString** argument which will contain the result string returned by the server.

cbResult

The maximum number of characters that may be copied into the result string buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is the length of the result string. If a value of zero is returned, this means that no result string was sent by the server. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetResultString** method is most useful when an error occurs because the server will typically include a brief description of the cause of the error. This can then be parsed by the application or displayed to the user. The result string is updated each time the client sends a command to the server and then calls **GetResultCode** to obtain the result code for the operation.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[Command](#), [GetResultCode](#)

CFtpClient::GetSecurityInformation Method

```
BOOL GetSecurityInformation(  
    LPSECURITYINFO lpSecurityInfo  
);
```

The **GetSecurityInformation** method returns security protocol, encryption and certificate information about the current client connection.

Parameters

lpSecurityInfo

A pointer to a [SECURITYINFO](#) structure which contains information about the current client connection. The *dwSize* member of this structure must be initialized to the size of the structure before passing the address of the structure to this method.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method is used to obtain security related information about the current client connection to the server. It can be used to determine if a secure connection has been established, what security protocol was selected, and information about the server certificate. Note that a secure connection has not been established, the *dwProtocol* structure member will contain the value SECURITY_PROTOCOL_NONE.

Example

The following example notifies the user if the connection is secure or not:

```
SECURITYINFO securityInfo;  
securityInfo.dwSize = sizeof(SECURITYINFO);  
  
if (pClient->GetSecurityInformation(&securityInfo))  
{  
    if (securityInfo.dwProtocol == SECURITY_PROTOCOL_NONE)  
    {  
        MessageBox(NULL, _T("The connection is not secure"),  
                    _T("Connection"), MB_OK);  
    }  
    else  
    {  
        if (securityInfo.dwCertStatus == SECURITY_CERTIFICATE_VALID)  
        {  
            MessageBox(NULL, _T("The connection is secure"),  
                        _T("Connection"), MB_OK);  
        }  
        else  
        {  
            MessageBox(NULL, _T("The server certificate not valid"),  
                        _T("Connection"), MB_OK);  
        }  
    }  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Connect](#), [CreateSecurityCredentials](#), [SECURITYINFO](#)

CFtpClient::GetServerInformation Method

```
INT GetServerInformation(  
    LPTSTR lpszSystemInfo,  
    INT nMaxLength  
);
```

The **GetServerInformation** method returns information about the server, typically including the operating system type, version and platform.

Parameters

lpszSystemInfo

A pointer to the buffer that will contain the system information returned by the server.

nMaxLength

The maximum number of characters that can be copied into the buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the SYST command to the server. The first word will identify the type of operating system. The format for the remaining information depends on the server type. Typically it is a description of the operating system version and hardware platform.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Connect](#), [GetClientQuota](#), [GetServerStatus](#), [GetServerTimeZone](#), [GetServerType](#)

CFtpClient::GetServerStatus Method

```
INT GetServerStatus(  
    LPTSTR lpszStatus,  
    INT nMaxLength  
);  
  
INT GetServerStatus(  
    CString& strStatus  
);
```

The **GetServerStatus** method requests that the server return status information about itself.

Parameters

lpszStatus

A pointer to the buffer that will contain the system status returned by the server. The alternate form of this method also accepts a **CString** object which will contain the system status string.

nMaxLength

The maximum number of characters that can be copied into the buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the STAT command to the server. The format for the information returned depends on the server type. Typically it is a description of the server platform, version, current user and file transfer options.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetServerInformation](#), [GetServerType](#)

CFtpClient::GetServerTimeZone Method

```
INT GetServerTimeZone(  
    LPLONG lpnTimeZone  
);
```

The **GetServerTimeZone** method returns the timezone for the current server.

Parameters

lpnTimeZone

A pointer to a signed long integer which will contain the timezone offset in seconds.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **FtpGetLastError**.

Remarks

This method sends the SITE ZONE command to the server to determine its timezone. The value returned is expressed as the number of seconds offset from Coordinated Universal Time (UTC). A positive value specifies a time west of UTC, while a negative value specifies a time east of UTC. For example, a value of 28800 would specify an offset of 8 hours west of UTC, which is the Pacific timezone.

The SIZE ZONE command is an extension that is not supported by all servers. If the server timezone cannot be determined, the method will fail and the value pointed to by the *lpnTimeZone* parameter will be zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[GetClientQuota](#), [GetServerInformation](#), [GetServerStatus](#)

CFtpClient::GetServerType Method

INT GetServerType();

The **GetServerType** method returns the type of server the client has connected to.

Parameters

None.

Return Value

If the method succeeds, the return value is a numeric value which indicates the server type. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the SYST command to the server to determine the server type. The following server types are recognized by the library:

Value	Description
FTP_SERVER_UNKNOWN	The server type could not be determined by issuing the SYST command. The server may not support the command, or the command may only be allowed when issued by an authenticated user.
FTP_SERVER_MSDOS	The server is running on an MS-DOS based operating system. The server expects file pathing and naming conventions according to the standard MS-DOS format and returns directory listings similar to the output of the DIR command.
FTP_SERVER_WINDOWS	The server is running on a Windows based operating system. The server expects file pathing and naming conventions according to the standard Windows long filename format, and returns directory listings similar to the output of the DIR command. Note that Windows servers may be configured to return file and directory information in a format similar to UNIX systems, in which case the system may be identified as UNIX even though it is actually running on a Windows platform.
FTP_SERVER_VMS	The server is running on a DEC VMS based operating system. The server expects file pathing and naming conventions specific to that operating system. Note that VMS servers may be configured to return file and directory information in a format similar to UNIX systems, in which case the system may be identified as UNIX even though it is actually running on a VMS platform.
FTP_SERVER_NETWARE	The server is running on a NetWare based operating system. The server expects file pathing and naming conventions similar to the standard Windows long filename format, and returns directory listings that are similar to UNIX systems with the exception of the access and permissions flags for the file. Note that a NetWare system may return listings in different formats based on the filesystem and site specific options specified.

FTP_SERVER_OTHER	The server type was not recognized. An attempt will be made to automatically determine the correct file pathing and naming conventions used by the server. To obtain a list of files on the server, it may be necessary to use the SetDirectoryFormat method to specify the directory listing format.
------------------	--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[GetClientQuota](#), [GetServerInformation](#), [GetServerStatus](#), [SetDirectoryFormat](#)

CFtpClient::GetStatus Method

```
INT GetStatus();
```

The **GetStatus** method the current status of the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is the client status code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetStatus** method returns a numeric code which identifies the current state of the client session. The following values may be returned:

Value	Description
FTP_STATUS_UNUSED	No connection has been established.
FTP_STATUS_IDLE	The client is current idle and not sending or receiving data.
FTP_STATUS_CONNECT	The client is establishing a connection with the server.
FTP_STATUS_READ	The client is reading data from the server.
FTP_STATUS_WRITE	The client is writing data to the server.
FTP_STATUS_DISCONNECT	The client is disconnecting from the server.
FTP_STATUS_OPENFILE	The client is opening a data connection to the server.
FTP_STATUS_CLOSEFILE	The client is closing the data connection to the server.
FTP_STATUS_GETFILE	The client is downloading a file from the server.
FTP_STATUS_PUTFILE	The client is uploading a file to the server.
FTP_STATUS_FILELIST	The client is retrieving a file listing from the server.

In a multithreaded application, any thread in the current process may call this method to obtain status information for the specified client session. To obtain status information about a file transfer, use the **GetTransferStatus** method.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** csftpv11.lib

See Also

[IsBlocking](#), [IsReadable](#), [IsWritable](#), [GetTransferStatus](#)

CFtpClient::GetText Method

```
INT GetText(  
    LPCTSTR lpszRemoteFile,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

The **GetText** method copies the contents of a text file on the server to the specified string buffer.

Parameters

lpszRemoteFile

A pointer to a string that specifies a text file on the server. The file pathing and naming conventions must be that of the host operating system.

lpszBuffer

A pointer to a string buffer which will contain the contents of the text file when the method returns. This buffer should be large enough to store the contents of the file, including a terminating null character. This parameter cannot be NULL.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. This value must be larger than zero. If this value is smaller than the actual size of the text file, the data returned will be truncated.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetText** method is used to download a text file and store the contents in a string buffer. This method will always set the file type to FILE_TYPE_ASCII before downloading the file, and will restore the default file type before the method returns. Because binary files can include embedded null characters, this method should only be used with known text files.

This method has been included as a convenience for applications that need to retrieve relatively small text files and manipulate the contents as a string. If the Unicode version of this method is called, the contents of the text file is automatically converted to a Unicode string. If the size of the file is unknown or the text file is very large, it is recommended that you use the **GetData** or **GetFile** methods.

If you use the **GetFileSize** method to determine how large the string buffer should be prior to calling this method, it is important to be aware that the actual number of characters may differ based on the end-of-line conventions used by the host operating system. For example, if you call **GetFileSize** to obtain the size of a text file on a UNIX system, the value will not be large enough to store the complete file because UNIX uses a single linefeed (LF) character to indicate the end-of-line, while a Windows system will use a carriage-return and linefeed (CRLF) pair. To accommodate this difference, you should always allocate extra memory for the string buffer to store the additional end-of-line characters.

FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus**

method.

Example

```
LPTSTR lpszBuffer = (LPTSTR)calloc(MAXFILESIZE, sizeof(TCHAR));

if (lpszBuffer == NULL)
    return;

nResult = pClient->GetText(lpszRemoteFile, lpszBuffer, MAXFILESIZE);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::GetTimeout Method

```
INT GetTimeout();
```

The **GetTimeout** method returns the number of seconds the client will wait for a response from the server. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

None.

Return Value

If the method succeeds, the return value is the timeout period in seconds. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections. A value of zero indicates that the default timeout period of 20 seconds should be used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[Connect](#), [IsReadable](#), [IsWritable](#), [Read](#), [SetTimeout](#), [Write](#)

CFtpClient::GetTransferStatus Method

```
INT GetTransferStatus(  
    LPFTPTRANSFERSTATUS LpStatus  
);  
  
INT GetTransferStatus(  
    LPFTPTRANSFERSTATUSEX LpStatus  
);
```

The **GetTransferStatus** method returns information about the current file transfer in progress.

Parameters

LpStatus

A pointer to an [FTPTRANSFERSTATUS](#) or [FTPTRANSFERSTATUSEX](#) structure which contains information about the status of the current file transfer.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **GetTransferStatus** method returns information about the current file transfer, including the average number of bytes transferred per second and the estimated amount of time until the transfer completes. If there is no file currently being transferred, this method will return the status of the last successful transfer made by the client.

The *dwBytesTotal* and *dwBytesCopied* members of the **FTPTRANSFERSTATUSEX** structure are declared as unsigned 64-bit integers rather than 32-bit integers. To obtain accurate file transfer information, this extended version of the structure should be used with files that are larger than 4GiB.

In a multithreaded application, any thread in the current process may call this method to obtain status information for the specified client session.

If the option `FTP_OPTION_HIRES_TIMER` has been specified when connecting to the server, the values of the *dwTimeElapsed* and *dwTimeEstimated* members of the **FTPTRANSFERSTATUS** and **FTPTRANSFERSTATUSEX** structure will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small files over a fast network connection.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnableEvents](#), [GetFileStatus](#), [GetStatus](#), [RegisterEvent](#)

CFtpClient::IsBlocking Method

BOOL IsBlocking();

The **IsBlocking** method is used to determine if the client is currently performing a blocking operation.

Parameters

None.

Return Value

If the client is performing a blocking operation, the method returns a non-zero value. If the client is not performing a blocking operation, or the client handle is invalid, the method returns zero.

Remarks

Because a blocking operation can allow the application to be re-entered (for example, by pressing a button while the operation is being performed), it is possible that another blocking method may be called while it is in progress. Since only one thread of execution may perform a blocking operation at any one time, an error would occur. The **IsBlocking** method can be used to determine if the client is already blocked, and if so, take some other action (such as warning the user that they must wait for the operation to complete).

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Cancel](#), [GetStatus](#), [IsConnected](#), [IsInitialized](#), [IsReadable](#), [IsWritable](#), [Read](#), [Write](#)

CFtpClient::IsConnected Method

BOOL IsConnected();

The **IsConnected** method is used to determine if the client is currently connected to a server.

Parameters

None.

Return Value

If the client is connected to a server, the method returns a non-zero value. If the client is not connected, or the client handle is invalid, the method returns zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[GetStatus](#), [IsBlocking](#), [IsInitialized](#), [IsReadable](#), [IsWritable](#)

CFtpClient::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[CFtpClient](#), [IsBlocking](#), [IsConnected](#)

CFtpClient::IsReadable Method

```
BOOL IsReadable(  
    INT nTimeout,  
    LPDWORD lpdwAvail  
);
```

The **IsReadable** method is used to determine if data is available to be read from the server.

Parameters

nTimeout

Timeout for server response, in seconds. A value of zero specifies that the connection should be polled without blocking the current thread.

lpdwAvail

A pointer to an unsigned integer which will contain the number of bytes available to read. This parameter may be NULL if this information is not required.

Return Value

If the client can read data from the server within the specified timeout period, the function returns a non-zero value. If the client cannot read any data, the method returns zero.

Remarks

On some platforms, this value will not exceed the size of the receive buffer (typically 64K bytes). Because of differences between TCP/IP stack implementations, it is not recommended that your application exclusively depend on this value to determine the exact number of bytes available. Instead, it should be used as a general indicator that there is data available to be read.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[GetStatus](#), [IsBlocking](#), [IsConnected](#), [IsInitialized](#), [IsWritable](#), [Write](#)

CFtpClient::IsWritable Method

```
BOOL IsWritable(  
    INT nTimeout  
);
```

The **IsWritable** method is used to determine if data can be written to the server.

Parameters

nTimeout

Timeout for server response, in seconds. A value of zero specifies that the connection should be polled without blocking the current thread.

Return Value

If the client can write data to the server within the specified timeout period, the method returns a non-zero value. If the client cannot write any data, the method returns zero.

Remarks

Although this method can be used to determine if some amount of data can be sent to the remote process it does not indicate the amount of data that can be written without blocking the client. In most cases, it is recommended that large amounts of data be broken into smaller logical blocks, typically some multiple of 512 bytes in length.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

CFtpClient::Login Method

```
INT Login(  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    LPCTSTR lpszAccount  
);
```

The **Login** method authenticates the specified user in on the server. This method must be called after the connection has been established, and before attempting to transfer files or perform any other method on the server.

Parameters

lpszUserName

Points to a string that specifies the user name to be used to authenticate the current client session. If this parameter is NULL or an empty string, then the login is considered to be anonymous.

lpszPassword

Points to a string that specifies the password to be used to authenticate the current client session. This parameter may be NULL or an empty string if no password is required for the specified user, or if no username has been specified.

lpszAccount

Points to a string that specifies the account name to be used to authenticate the current client session. This parameter may be NULL or an empty string if no account name is required for the specified user.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Some public FTP servers support anonymous logins, where a username and password are not required to access the server. In this case, both the *lpszUserName* and *lpszPassword* parameters can be NULL or specify empty strings. In most cases, access to the server using an anonymous login is restricted, with clients only having permission to download files. Servers may also restrict the maximum number of anonymous sessions that may be logged in at one time.

This method should only be used after calling the **Logout** method, enabling you to log in as another user during the same session. Not all servers will permit a client to change user credentials during the same session. In most cases, it is preferable to disconnect from the server and re-connect using the new credentials rather than using this method.

This method is not supported with secure connections using the SSH protocol.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::Logout Method

INT Logout();

The **Logout** method logs out the user associated with the current client session.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **Logout** method is used when the client wants to re-authenticate using a new username and password. Before any further action may be taken, other than disconnecting from the server, the **Login** method must be called to re-authenticate the client.

It is not necessary to call this method prior to disconnecting from the server because the user current user is automatically logged out when the **Disconnect** method is called.

This method is not supported with secure connections using the SSH protocol.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::MountStructure Method

```
INT MountStructure(  
    LPCTSTR lpszFileSystem  
);
```

The **MountStructure** method mounts a different file system or other directory data structure on the server.

Parameters

lpszFileSystem

A pointer to a string which specifies the file system to mount on the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method sends the SMNT command to the server, which may not be supported on some platforms. Use of this command typically requires that the user have administrator privileges on the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[CreateDirectory](#), [RemoveDirectory](#)

CFtpClient::OpenDirectory Method

```
INT OpenDirectory(  
    LPCTSTR lpszDirectory  
);
```

The **OpenDirectory** method opens the specified directory on the server.

Parameters

lpszDirectory

Pointer to the name of the directory that will be opened. The format of the directory name must match the filename conventions used by the server. If a NULL pointer or an empty string is specified, then the current working directory is opened.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **OpenDirectory** method opens the specified directory on the server using the LIST command. The contents of the directory can be read using the **GetFirstFile** and **GetNextFile** methods. The directory listing is returned on the data channel in one of several different formats. The library can recognize listing formats generated by UNIX, VMS and Windows servers, as well as those of other servers which emulate one of those common formats. Once the complete directory listing has been read, the directory must be closed by calling the **CloseDirectory** method.

Because the directory listing is returned on the data channel, a file transfer cannot be performed while the directory is in the process of being read by the client. Applications which need to collect a list of files to download should first open the directory, read the contents and store the file names in an array. After the directory has been closed, the application can then start transferring the files to the local system.

Some servers may not support file listings for any directory other than the current working directory. If an error is returned when specifying a directory name, try changing the current working directory using the **ChangeDirectory** method and then call this method again, passing NULL or an empty string as the *lpszDirectory* parameter.

To obtain a list of all files in a directory using a single function call, use the **EnumFiles** method. If the server lists files in a format that is not recognized by the library, the **GetFileList** method can be used to obtain an unparsed file listing from the server.

Example

```
if (pClient->OpenDirectory() != FTP_ERROR)  
{  
    FTPFILESTATUS ftpFile;  
    BOOL bResult;  
  
    bResult = pClient->GetFirstFile(&ftpFile);  
    while (bResult)  
    {  
        // The ftpFile structure contains information about the file  
        bResult = pClient->GetNextFile(&ftpFile);  
    }  
}
```

```
pClient->CloseDirectory();  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::OpenFile Method

```
INT OpenFile(  
    LPCTSTR lpszFileName,  
    DWORD dwOpenMode,  
    DWORD dwOffset  
);
```

The **OpenFile** method creates or opens the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file to create or open. The file pathing and name conventions must be that of the server.

dwOpenMode

Specifies the type of access to the file. An application can open a file for reading, create a new file or append data to an existing file. This parameter should be one of the following values.

Value	Description
FTP_FILE_READ	The file is opened for reading on the server. A data channel is created and the contents of the file are returned to the client.
FTP_FILE_WRITE	The file is opened for writing on the server. If the file does not exist, it will be created. If it does exist, it will be overwritten.
FTP_FILE_APPEND	The file is opened for writing on the server. All data will be appended to the end of the file.

dwOffset

A byte offset which specifies where the file transfer should begin. The default value of zero specifies that the file transfer should start at the beginning of the file. A value greater than zero is typically used to restart a transfer that has not completed successfully. Note that specifying a non-zero offset using FTP requires that the server support the REST command to restart transfers.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Only one file may be opened at a time for each client session. Attempting to perform an action such as uploading or downloading another file while a file is currently open will result in an error. Typically this indicates that the application failed to call the **CloseFile** method.

It is strongly recommended that most applications use the **GetFile** or **PutFile** methods to perform file transfers. These methods are easier to use, and have internal optimizations that improves the overall data transfer rate when compared to implementing the file transfer code in your own application.

When a file is created on the server, the file ownership and access rights are determined by the server. Some servers may provide a method to change these attributes through site-specific commands. Refer to the server's operating system documentation for more information about what commands may be available.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::ProxyConnect Method

```
HCLIENT ProxyConnect(
    UINT nProxyType,
    LPCTSTR lpszProxyHost,
    UINT nProxyPort,
    LPCTSTR lpszProxyUser,
    LPCTSTR lpszProxyPassword,
    LPCTSTR lpszRemoteHost,
    UINT nRemotePort,
    UINT nTimeout,
    DWORD dwOptions
);
```

The **ProxyConnect** method establishes a connection through a proxy server.

Parameters

nProxyType
An identifier which specifies the type of proxy server that is being connected to. This value must be defined as one of the following values:

Value	Description
FTP_PROXY_NONE	This value specifies that no proxy server is being used. In this case, the Connect method is called directly, ignoring the proxy parameters.
FTP_PROXY_USER	This value specifies that the client is not logged into the proxy server. The USER command is sent in the format username@ftpsite followed by the password. This is the format used with the Gauntlet proxy server.
FTP_PROXY_LOGIN	This value specifies that the client is logged into the proxy server. The USER command is then sent in the format username@ftpsite followed by the password. This is the format used by the InterLock proxy server.
FTP_PROXY_OPEN	This value specifies that the client is not logged into the proxy server. The OPEN command is sent specifying the host name, followed by the username and password.
FTP_PROXY_SITE	This value specifies that the client is logged into the server. The SITE command is sent, specifying the host name, followed by the username and the password.
FTP_PROXY_OTHER	This special proxy type specifies that another, undefined proxy server is being used. The client connects to the proxy host, but does not attempt to authenticate the client. The application is responsible for negotiating with the proxy server, typically using the Command method to send specific command sequences.

lpszProxyHost
A pointer to the name of the proxy server to connect through; this may be a fully-qualified domain name or an IP address.

nProxyPort

The port number the proxy server is listening on; a value of zero specifies that the default port number should be used.

lpszProxyUser

A pointer to the user name used to authenticate the client on the proxy server. Not all proxy servers require this information; it is recommended that you consult the proxy server documentation to determine if a username is required.

lpszProxyPassword

A pointer to the password used to authenticate the client on the proxy server. Not all proxy servers require this information; it is recommended that you consult the proxy server documentation to determine if a password is required.

lpszRemoteHost

A pointer to the name of the server to connect to; this may be a fully-qualified domain name or an IP address.

nRemotePort

The port number the server is listening on; a value of zero specifies that the default port number should be used. For standard connections, the default port number is 21. For secure connections, the default port number is 990.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the client should attempt to establish the data connection with the server. When the client uploads or downloads a file, normally the server establishes a second connection back to the client which is used to transfer the file data. However, if the local system is behind a firewall or a NAT router, the server may not be able to create the data connection and the transfer will fail. By specifying this option, it forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the client should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.

FTP_OPTION_NOAUTH	This option specifies the server does not require authentication, or that it requires an alternate authentication method. When this option is used, the client connection is flagged as authenticated as soon as the connection to the server has been established. Note that using this option to bypass authentication may result in subsequent errors when attempting to retrieve a directory listing or transfer a file. It is recommended that you consult the technical reference documentation for the server to determine its specific authentication requirements.
FTP_OPTION_VIRTUALHOST	This option specifies the server supports virtual hosting, where multiple domains are hosted by a server using the same external IP address. If this option is enabled, the client will send the HOST command to the server upon establishing a connection.
FTP_OPTION_VERIFY	This option specifies that file transfers should be automatically verified after the transfer has completed. If the server supports the XMD5 command, the transfer will be verified by calculating an MD5 hash of the file contents. If the server does not support the XMD5 command, but does support the XCRC command, the transfer will be verified by calculating a CRC32 checksum of the file contents. If neither the XMD5 or XCRC commands are supported, the transfer is verified by comparing the size of the file. Automatic file verification is only performed for binary mode transfers because of the end-of-line conversion that may occur when text files are uploaded or downloaded.
FTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
FTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. This option is the same as specifying FTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.
FTP_OPTION_SECURE_IMPLICIT	This option specifies the client should attempt to immediately establish secure TLS connection with the server. This option is typically used when connecting to a server on port 990, which is the default port number used for FTPS.
FTP_OPTION_SECURE_EXPLICIT	This option specifies the client should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure

	connection. This option is typically used when connecting to the server on ports other than 990.
FTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
FTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established. This option also forces all connections to be outbound and enables the firewall compatibility features in the client.
FTP_OPTION_KEEPALIVE_DATA	This option specifies the client should attempt to keep the control connection active during a file transfer. Normally, when a data transfer is in progress, no additional commands are issued on the control channel until the transfer completes. Specifying this option automatically enables the FTP_OPTION_KEEPALIVE option and forces the client to continue to issue NOOP commands during the file transfer. This option only applies to FTP and FTPS connections and has no effect on connections using SFTP (SSH).
FTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
FTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the handle is synchronized across multiple threads.
FTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller files being uploaded or downloaded using fast network connections.
FTP_OPTION_TLS_REUSE	This option specifies that TLS session reuse should be enabled for secure connections. This option is only supported on Windows 8.1 or Windows Server 2012 R2

	and later platforms, and it should only be used when explicitly required by the server. This option is not compatible with servers built using OpenSSL 1.0.2 and earlier versions which do not provide Extended Master Secret (EMS) support as outlined in RFC7627.
--	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Return Value

If the method succeeds, the return value is a handle to a client session. If the method fails, the return value is `INVALID_CLIENT`. To get extended error information, call **GetLastError**.

Remarks

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **ProxyConnect** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

The username and password that is used to authenticate the client with the proxy server are not the same as those used to login to the target server. Once a connection has been established with the proxy server, the client must call the **Login** method to actually login to the server and begin a file transfer.

If the `FTP_OPTION_KEEPALIVE` option is specified, a background worker thread will be created to monitor the command channel and periodically send NOOP commands to the server if no commands have been sent recently. This can prevent the server from terminating the client connection during idle periods where no commands are being issued. However, it is important to keep in mind that many servers can be configured to also limit the total amount of time a client can be connected to the server, as well as the amount of time permitted between file transfers. If the server does not respond to the NOOP command, this option will be automatically disabled for the remainder of the client session.

If the `FTP_OPTION_SECURE_EXPLICIT` option is specified, the client will first send an AUTH TLS command to the server. If the server does not accept this command, it will then send an AUTH SSL command. If both commands are rejected by the server, an explicit TLS session cannot be established. By default, both the command and data channels will be encrypted when a secure connection is established. To change this, use the **SetChannelMode** method.

The ***dwOptions*** argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the `FTP_OPTION_FREETHREAD` option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::PutData Method

```
INT PutData(  
    LPCTSTR lpszRemoteFile,  
    LPBYTE lpBuffer,  
    DWORD dwLength  
);  
  
INT PutData(  
    LPCTSTR lpszRemoteFile,  
    LPCTSTR lpszBuffer  
);
```

The **PutData** method transfers the contents of the specified buffer to a file on the server.

Parameters

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be created, overwritten or appended to. The file naming conventions must be that of the host operating system.

lpBuffer

A pointer to the data that will be copied to the server and stored in the specified file. An alternate version of the method uses a pointer to a string buffer where all of the bytes will be written to the server up to, but not including, the terminating null character.

dwLength

The number of bytes to copy from the buffer.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpClient::PutFile Method

```
INT PutFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions  
    DWORD dwOffset  
);
```

The **PutFile** method transfers the specified file on the local system to the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the file that will be transferred from the local system. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be created, overwritten or appended to. The file naming conventions must be that of the host operating system.

dwOptions

An unsigned integer that specifies one or more options. This parameter may be any one of the following values:

Value	Description
FTP_TRANSFER_DEFAULT	This option specifies the default transfer mode should be used. If the remote file exists, it will be overwritten with the contents of the uploaded file.
FTP_TRANSFER_APPEND	This option specifies that if the remote file exists, the contents of the local file is appended to the remote file. If the remote file does not exist, it is created.

dwOffset

A byte offset which specifies where the file transfer should begin. The default value of zero specifies that the file transfer should start at the beginning of the file. A value greater than zero is typically used to restart a transfer that has not completed successfully. Note that specifying a non-zero offset requires that the server support the REST command to restart transfers.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::PutMultipleFiles Method

```
INT PutMultipleFiles(  
    LPCTSTR lpszLocalDirectory,  
    LPCTSTR lpszRemoteDirectory,  
    LPCTSTR lpszFileMask  
);
```

The **PutMultipleFiles** method copies one or more files from the local host to the server, using the specified wildcard.

Parameters

lpszLocalDirectory

Pointer to a string which specifies the local directory where the files will be copied from. A NULL pointer or empty string specifies that files should be copied from the current working directory.

lpszRemoteDirectory

Pointer to a string which specifies the remote directory where the files will be copied to. A NULL pointer or empty string specifies that the files should be copied to the current working directory on the server.

lpszFileMask

Pointer to a string which specifies the files that are to be copied from the local system to the server. The file mask should follow the Windows conventions used for wildcard file matches.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PutMultipleFiles** method is used to transfer files from the local host to the server which match a specified wildcard file mask. All files will be transferred using the current file type as specified by the **SetFileType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ChangeDirectory](#), [GetFile](#), [GetMultipleFiles](#), [PutFile](#)

CFtpClient::PutText Method

```
INT PutText(  
    LPCTSTR lpszRemoteFile,  
    LPCTSTR lpszBuffer  
);
```

The **PutText** method creates a text file on the server using the contents of a string buffer.

Parameters

lpszRemoteFile

A pointer to a string that specifies the text file on the server that will be created or overwritten. The file pathing and name conventions must be that of the server.

lpszBuffer

A pointer to a string that contains the text that will be stored in the file.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PutText** method is used to create a text file on the server from the contents of a string. If the specified file already exists on the server, its contents will be overwritten. This method will always set the file type to FILE_TYPE_ASCII before creating the file, and will restore the default file type before the method returns.

If the Unicode version of this method is called, the string will be converted to UTF-8 and then uploaded to the server. If you wish to store the contents of the string as UTF-16 Unicode on the server, you must set the current file type to FILE_TYPE_IMAGE and use the **PutData** method. This method should never be used to upload binary data.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the FTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::Read Method

```
INT Read(  
    LPBYTE lpBuffer,  
    INT cbBuffer  
);  
  
INT Read(  
    CString& strBuffer,  
    INT cbBuffer  
);
```

The **Read** method reads the specified number of bytes from the client socket and copies them into the buffer. The data may be of any type, and is not terminated with a null character.

Parameters

lpBuffer

Pointer to the buffer in which the data will be copied. An alternate form of the method accepts a **CString** object which will contain the data returned from the server.

cbBuffer

The maximum number of bytes to read and copy into the specified buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of bytes actually read. A return value of zero indicates that the server has closed the connection and there is no more data available to be read. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

When **Read** is called and the client is in non-blocking mode, it is possible that the method will fail because there is no available data to read at that time. This should not be considered a fatal error. Instead, the application should simply wait to receive the next asynchronous notification that data is available.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::RegisterEvent Method

```
INT RegisterEvent(  
    UINT nEventId,  
    FTPEVENTPROC LpEventProc,  
    DWORD_PTR dwParam  
);
```

The **RegisterEvent** method registers an event handler for the specified event.

Parameters

nEventId

An unsigned integer which specifies which event should be registered with the specified callback function. One of the following values may be used:

Value	Description
FTP_EVENT_CONNECT	The control connection to the server has completed.
FTP_EVENT_DISCONNECT	The server has closed the control connection to the client. The client should read any remaining data and disconnect.
FTP_EVENT_OPENFILE	The data connection to the server has completed.
FTP_EVENT_CLOSEFILE	The server has closed the data connection to the client. The client should read any remaining data and close the data channel.
FTP_EVENT_READFILE	Data is available to read by the calling process. No additional messages will be posted until the client has read at least some of the data. This event is only generated if the client is in asynchronous mode.
FTP_EVENT_WRITEFILE	The client can now write data. This notification is sent after a connection has been established, or after a previous attempt to write data has failed because it would result in a blocking operation. This event is only generated if the client is in asynchronous mode.
FTP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
FTP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.
FTP_EVENT_COMMAND	A command has been issued by the client and the server response has been received and processed. This event can be used to log the result codes and messages returned by the server in response to actions taken by the client.
FTP_EVENT_PROGRESS	The client is in the process of sending or receiving a file on the data channel. This event is called periodically during a transfer so that the client can update any user interface components such as a status control or progress bar.
FTP_EVENT_GETFILE	This event is generated when a file download has completed. If multiple files are being downloaded, this event will be generated for each file.

FTP_EVENT_PUTFILE	This event is generated when a file upload has completed. If multiple files are being uploaded, this event will be generated for each file.
FTP_EVENT_QUEUE	This event is generated during a queued file transfer. It only occurs when a file is being transferred using the CftpQueue class and the internal state of the queue has changed. The handle passed to this event will be a handle to the queue, not a client connection to the server.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **FtpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function. If the application targets the x86 (32-bit) platform, this parameter must be a 32-bit unsigned integer. If the application targets the x64 (64-bit) platform, this parameter must be a 64-bit unsigned integer.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **RegisterEvent** method associates a callback function with a specific event. The event handler is an **FtpEventProc** function that is invoked when the event occurs. Arguments are passed to the function to identify the client session, the event type and the user-defined value specified when the event handler is registered. If the event occurs because of an error condition, the error code will be provided to the handler.

This method is typically used to register an event handler that is invoked while a file is being uploaded or downloaded. The FTP_EVENT_PROGRESS event will only be generated periodically during the transfer to ensure the application is not flooded with event notifications. It is guaranteed that at least one FTP_EVENT_PROGRESS notification will occur at the beginning of the transfer, and one at the end of the transfer when it has completed.

The callback function specified by the *lpEventProc* parameter must be declared using the **__stdcall** calling convention. This ensures the arguments passed to the event handler are pushed on to the stack in the correct order. Failure to use the correct calling convention will corrupt the stack and cause the application to terminate abnormally.

The *dwParam* parameter is commonly used to identify the class instance which is associated with the event that has occurred. Applications will cast the **this** pointer to a DWORD_PTR value when calling this function, and then the event handler will cast it back to a pointer to the class instance. This gives the handler access to the class member variables and methods.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

CFtpClient::RegisterFileType Method

```
BOOL RegisterFileType(  
    LPCTSTR lpszExtension,  
    UINT nFileType  
);
```

The **RegisterFileType** method associates a file name extension with a specific file type.

Parameters

lpszExtension

A pointer to a null terminated string which specifies the file name extension. If this parameter is NULL or points to an empty string, the default file type will be changed for the client session.

nFileType

Specifies the type of file associated with the file extension. This parameter can be one of the following values.

Value	Description
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
FILE_TYPE_EBCDIC	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server.
FILE_TYPE_IMAGE	The file is a binary image and no data conversion of any type is performed on the file. This is typically the default file type for data file transfers. If the type of file that is being transferred is unknown, this file type should always be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **RegisterFileType** method is used to associate specific file types with file name extensions. The library has an internal list of standard text file extensions which it automatically recognizes. This method can be used to extend or modify that list for the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetAutoFileType](#), [OpenFile](#), [SetFileMode](#), [SetFileStructure](#), [SetFileType](#), [SetPassiveMode](#)

CFtpClient::RemoveDirectory Method

```
INT RemoveDirectory(  
    LPCTSTR lpszDirectory  
);
```

The **RemoveDirectory** method removes the specified directory on the server.

Parameters

lpszDirectory

Points to a string that specifies the name of the directory. The file pathing and name conventions must be that of the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the RMD command to create the directory. The user must have the appropriate permission to remove the specified directory. Most servers will not permit you to remove a directory if it contains one or more files.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ChangeDirectory](#), [CreateDirectory](#), [DeleteFile](#), [GetDirectory](#)

CFtpClient::RenameFile Method

```
INT RenameFile(  
    LPCTSTR lpszOldFileName,  
    LPCTSTR lpszNewFileName  
);
```

The **RenameFile** method renames or moves the specified file on the server. The original file must exist and the current user must have the appropriate permissions to change the file name.

Parameters

lpszOldFileName

A null-terminated string which specifies the name of the remote file to rename or move. This parameter cannot be NULL or a zero-length string and the file must exist on the server. The file path and name must match the conventions used on the server.

lpszNewFileName

A null-terminated string which specifies the new name for the file. This parameter cannot be NULL or a zero-length string. The file path and name must match the conventions used on the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the *lpszNewFileName* parameter specifies a file which already exists on the server, the contents of that file will be deleted and replaced by the contents of the file specified by *lpszOldFileName*. If you want to prevent this from occurring, your application can check if a file with the new name exists by calling the **GetFileStatus** method. If successful, you can warn the user the rename operation would delete the contents of the new file as a consequence of renaming the original file.

If the connection was established using the standard FTP or FTPS protocols, this method causes two separate commands to be sent to the server, RNFR and RNT0. If either command fails, the method will fail and return an error code. If the connection was established using SFTP (SSH) the client will request the server rename the file atomically by specifying the internal SSH_FXF_RENAME_ATOMIC option. If the server does not support this option and *lpszNewFileName* already exists on the server, this method will attempt to delete the file and retry the rename operation.

This method can be used to move a file from one folder to another on the server, as long as the user has the appropriate permissions required to perform the operation. If the new file name includes a path, that path must already exist on the server or the method will fail.

If the old and new file names specify folders instead of regular files, the server may or may not allow the operation, depending on the access rights for those folders and the server's configuration. Some servers may allow a simple rename operation within the same parent folder, but may not permit you to move the folder to another location in the filesystem.

There is no guarantee the rename operation will be performed in an atomic fashion if multiple client sessions attempt to rename the same file at the same time. For example, it is possible that one client could attempt to rename a file while another client is already in the process of moving the file to a new folder. In this case, the server may respond with an error indicating the file cannot be found, an access denied error or a general failure error.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::Reset Method

INT Reset();

The **Reset** method resets the client state and resynchronizes with the server. This method is typically called after an unexpected error has occurred, or an operation has been canceled.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The client cannot be reset while a file transfer is in progress or if the client is in a blocked state. To abort a file transfer, use the **Cancel** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Cancel](#)

CFtpClient::SetActivePorts Method

```
INT SetActivePorts(  
    UINT nLowPort,  
    UINT nHighPort  
);
```

The **SetActivePorts** method changes the range of local port numbers used for active mode file transfers.

Parameters

hClient

Handle to the client session.

nLowPort

An unsigned integer that specifies the low port number.

lpnHighPort

An unsigned integer that specifies the high port number.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **FtpGetLastError**.

Remarks

This method is used to modify the range of local port numbers used for active mode file transfers. When using active mode, the client listens for an inbound connection from the server rather than establishing an outbound connection for the data transfer. In most cases, passive mode transfers are preferred because they mitigate potential compatibility issues with firewalls and NAT routers.

If active mode transfers are required, the default port range used when listening for the server connection is between 1024 and 5000. This is the standard range of ephemeral ports used by the Windows operating system. However, under some circumstances that range of ports may be too small, or a firewall may be configured to deny inbound connections on ephemeral ports. In that case, the **SetActivePorts** method can be used to specify a different range of port numbers.

While it is technically permissible to assign the low and high port numbers to the same value, effectively specifying a single active port number, this is not recommended as it can cause the transfer to fail unexpectedly if multiple file transfers are performed. A minimum range of at least 1000 ports is recommended. For example, if you specify a low port value of 40000 then it is recommended that the high port value be at least 41000. The maximum port value is 65535.

To determine the current range of active port numbers being used, call the **GetActivePorts** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetActivePorts](#), [SetPassiveMode](#)

CFtpClient::SetBufferSize Method

```
INT SetBufferSize(  
    INT nBufferSize  
);
```

The **SetBufferSize** method sets the size in bytes of an internal buffer that will be used during data transfers.

Parameters

nBufferSize

The size of an internal buffer, in bytes. Any value greater than or equal to zero is acceptable. If *nBufferSize* is zero, then the default value of 4096 will be used. If *nBufferSize* is less than 256 bytes, the buffer size will be set to 256. The maximum value of *nBufferSize* is 1048576 (1Mb).

Return Value

If the method succeeds, the return value is the size of the internal buffer that will be used. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The speed of data transfers, particularly on uploads, may be sensitive to network type and configuration, and the size of the internal buffer used for data transfers. The default size of this buffer will result in good performance for a wide range of network characteristics. A larger buffer will not necessarily result in better performance. For example, a multiple of 1460, which is the typical Maximum Transmission Unit (MTU), may be optimal in many situations.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetBufferSize](#), [GetData](#), [GetFile](#), [PutData](#), [PutFile](#)

CFtpClient::SetChannelMode Method

```
INT SetChannelMode(  
    INT nMode  
);  
  
INT SetChannelMode(  
    INT nChannel,  
    INT nMode  
);
```

The **SetChannelMode** method changes the security mode for the specified communication channel.

Parameters

nChannel

An integer value which specifies which channel to return information for. If the first version of this method is called, then the data channel mode is modified; otherwise, the channel may be explicitly specified as one of the following values:

Value	Description
FTP_CHANNEL_COMMAND	Change information for the command channel. This is the communication channel used to send commands to the server and receive command result and status information from the server.
FTP_CHANNEL_DATA	Change information for the data channel. This is the communication channel used to send or receive data during a file transfer.

nMode

An integer value which specifies the new mode for the specified channel. It may be one of the following values:

Value	Description
FTP_CHANNEL_CLEAR	Data sent and received on this channel should not be encrypted.
FTP_CHANNEL_SECURE	Data sent and received on this channel should be encrypted. Specifying this option requires that a secure connection has already been established with the server.

Return Value

If the method succeeds, the return value is the previous mode for the specified channel. If the method fails, it will return **FTP_ERROR**. To get extended error information, call **FtpGetLastError**.

Remarks

The **SetChannelMode** method is used to change the default mode for the specified channel, and is typically used to control whether or not data is encrypted during a file transfer. If a standard, non-secure connection has been established with the server, an error will be returned if you specify the **FTP_CHANNEL_SECURE** mode for either channel.

If you have established a secure connection and then specify the **FTP_CHANNEL_CLEAR** mode for the command channel, the client will send the CCC command to the server to indicate that commands should no longer be encrypted. If the server does not support this command, an error will be returned

and the channel mode will remain unchanged. Once the command channel has been changed to clear mode, it cannot be changed back to secure mode. You must disconnect and re-connect to the server if you want to resume sending commands over an encrypted channel.

Changing the mode for the data channel requires that the server support the PROT command. If this command is not supported by the server, the method will fail and the channel mode will remain unchanged.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Import Library: csftpv11.lib

See Also

[GetChannelMode](#)

CFtpClient::SetDirectoryFormat Method

```
INT SetDirectoryFormat(  
    INT nFormatId  
);
```

The **SetDirectoryFormat** method is used to specify the format used by the server when returning a list of files. The format type is used internally by the library when parsing the file list returned by the server.

Parameters

nFormatId

An identifier used to specify the format of the file list returned by the server. The following values are recognized:

Value	Description
FTP_DIRECTORY_AUTO	This value specifies that the library should automatically determine the format of the file lists returned by the server. It is recommended that most applications use this value and allow the library to automatically determine the appropriate file listing format used by the server.
FTP_DIRECTORY_UNIX	This value specifies that the server returns file lists in the format commonly used by UNIX servers. Note that many servers can be configured to return file listings in this format, even if they are not actually a UNIX based platform. Consult the technical reference documentation for your server for more information.
FTP_DIRECTORY_MSDOS	This value specifies that the server returns file lists in the format commonly used by MS-DOS based systems. This includes Windows IIS servers. Long file names will be returned if supported by the underlying filesystem, such as NTFS or FAT32.
FTP_DIRECTORY_VMS	This value specifies that the server returns file lists in the format commonly used by VMS servers. Note that VMS servers can be configured to return a standard UNIX style listing in addition to the default VMS format.
FTP_DIRECTORY_STERLING_1	This value specifies that the server returns file listings in a proprietary format used by the Sterling server, which is used for EDI (Electronic Data Interchange) applications. This format uses a 13 byte status code.
FTP_DIRECTORY_STERLING_2	This value specifies that the server returns file listings in a proprietary format used by the Sterling server, which is used for EDI (Electronic Data Interchange) applications. This format uses a 10 byte status code.
FTP_DIRECTORY_NETWARE	This value specifies that the server returns file listings in a proprietary format used by NetWare servers. The format is similar to UNIX style listings except that file access and

	permissions are indicated by letter codes enclosed in brackets. This is the default format selected if the server identifies itself as a NetWare system.
FTP_DIRECTORY_MLSD	This value specifies that the server should return file listings in a machine-independent format as defined by RFC 3659. This format specifies file information as a sequence of name/value pairs, with the same format being used regardless of the operating system that the server is hosted on. Note that not all servers support this format, and some proxy servers may reject the command even if the remote server supports its use.

Return Value

If the method succeeds, the return value identifies the file list format used by the server. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

This method should only be used when the library cannot automatically determine the directory format returned by the server. To determine the format used by a server after a file list has been retrieved, use the **GetDirectoryFormat** method.

The default directory format is determined both by the server's operating system and by analyzing the format of the data returned by the server. If the library is unable to automatically determine the format, it will attempt to parse the list of files as though it is a UNIX style listing.

If the `FTP_DIRECTORY_MLSD` format is specified, the file information returned by the server may differ from the default output of the `LIST` command. For example, on a UNIX based FTP server, the output of the `LIST` command is typically the same format that is used by the `/bin/ls` command, where file names are sorted and hidden files are not listed. However, the `MLSD` command may return an unsorted list of files that includes hidden files and directories.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

CFtpClient::SetFeatures Method

```
DWORD SetFeatures(  
    DWORD dwFeatures  
);
```

The **SetFeatures** method specifies the server features available to the client.

Parameters

dwFeatures

An unsigned integer that specifies one or more features. Refer to the documentation for the **GetFeatures** method for a list of available features.

Return Value

If the method succeeds, the return value specifies the features that were previously enabled. If the method fails, it will return zero. Because it is possible that no features were enabled, a return value of zero does not always indicate an error. An application should call **GetLastError** to determine if an error code has been set.

Remarks

The **SetFeatures** method is used to enable a specific set of features for the current session. When a client connection is first established, all features are enabled based on the server type and the server's response to the FEAT command. However, as the client issues commands to the server, if the server reports that the command is unrecognized that feature will automatically be disabled in the client. To enable or disable a specific feature, an application can use the **EnableFeature** method.

For example, the first time an application calls the **GetFileSize** method to determine the size of a file, the library will try to use the SIZE command. If the server reports that the SIZE command is not available, that feature will be disabled and the library will not use the command again during the session unless it is explicitly re-enabled. This is designed to prevent the library from repeatedly sending invalid commands to a server, which may result in the server aborting the connection.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[EnableFeature](#), [GetFeatures](#)

CFtpClient::SetFileMode Method

```
INT SetFileMode(  
    UINT nMode  
);
```

The **SetFileMode** method sets the default file transfer mode for the current client session.

Parameters

nMode

Specifies the default type of data transfer mode for files being opened or created on the server. This parameter can be one of the following values.

Value	Description
FILE_MODE_STREAM	The data is transmitted as a stream of bytes. This is the default client transfer mode.
FILE_MODE_BLOCK	The data is transmitted as a series of data blocks preceded by one or more header bytes. This transfer mode is currently not supported.
FILE_MODE_COMPRESSED	The data is transmitted in compressed form. This transfer mode is currently not supported.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The file transfer mode should be set before a file is opened or created on the server. Once the transfer mode is set, it is in effect for all files that are subsequently opened or created.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** cstdlib11.h
- Import Library:** csftpv11.lib
- Unicode:** Implemented as Unicode and ANSI versions

See Also

[OpenFile](#), [SetFileStructure](#), [SetFileType](#), [SetPassiveMode](#)

CFtpClient::SetFileNameEncoding Method

```
INT SetFileNameEncoding(  
    INT nEncoding  
);
```

The **SetFileNameEncoding** method specifies what type of encoding will be used when file names are sent to the server.

Parameters

nEncoding

An integer value which specifies the encoding type. It may be one of the following values:

Value	Description
FTP_ENCODING_ANSI	File names are sent as 8-bit characters using the default character encoding for the current codepage. If the Unicode version of the functions are used, file names are converted from Unicode to ANSI using the current codepage before being sent to the server. This is the default encoding type.
FTP_ENCODING_UTF8	File names that contain non-ASCII characters are sent using UTF-8 encoding. This encoding type is only available on servers that advertise support for UTF-8 encoding and permit that encoding type to be enabled by the client.

Return Value

If the function succeeds, the return value is zero. If the function fails, the return value is FTP_ERROR. To get extended error information, call **FtpGetLastError**.

Remarks

The **SetFileNameEncoding** method can be used to enable UTF-8 encoding of file names, which provides improved support for the use of international character sets. However, the server must provide support for UTF-8 encoding by advertising it in response to the FEAT command and it must support the OPTS command which is used to enable UTF-8 encoding. If the server does not advertise support for UTF-8, or the OPTS command fails with an error, then this method will fail with an error and the encoding type will not change.

Although it is possible to use the **EnableFeature** method to explicitly enable the FTP_FEATURE_UTF8 feature, this is not recommended. If the server has not advertised support for UTF-8 encoding in response to the FEAT command, that typically indicates that UTF-8 encoding is not supported. Attempting to force UTF-8 encoding can result in unpredictable behavior when file names contain non-ASCII characters.

It is important to note that not all FTP servers support UTF-8 encoding, and in some cases servers which advertise support for UTF-8 encoding do not implement the feature correctly. For example, a server may allow a client to enable UTF-8 encoding, but once enabled will not permit the client to disable it. Some servers may advertise support for UTF-8 encoding, however if the underlying file system does not support UTF-8 encoded file names, any attempt to upload or download a file may fail with an error indicating that the file cannot be found or created.

Requirements

CFtpClient::SetFilePermissions Method

```
INT SetFilePermissions(  
    LPCTSTR lpszFileName,  
    DWORD dwPermissions  
);
```

The **SetFilePermissions** method returns information about the access permissions for a specific file on the server.

Parameters

lpszFileName

A pointer to a string which contains the name of the file to be updated. The filename cannot contain any wildcard characters.

dwPermissions

An unsigned integer which will specify the new access permissions for the file. The file permissions are represented as bit flags, and may be one or more of the following values combined with a bitwise Or operator:

Value	Description
FILE_OWNER_READ	The owner has permission to open the file for reading. If the current user is the owner of the file, this grants the user the right to download the file to the local system.
FILE_OWNER_WRITE	The owner has permission to open the file for writing. If the current user is the owner of the file, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_OWNER_EXECUTE	The owner has permission to execute the contents of the file. The file is typically either a binary executable, script or batch file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_GROUP_READ	Users in the specified group have permission to open the file for reading. If the current user is in the same group as the file owner, this grants the user the right to download the file.
FILE_GROUP_WRITE	Users in the specified group have permission to open the file for writing. On some platforms, this may also imply permission to delete the file. If the current user is in the same group as the file owner, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_GROUP_EXECUTE	Users in the specified group have permission to execute the contents of the file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_WORLD_READ	All users have permission to open the file for reading. This permission grants any user the right to download the file to the local system.

FILE_WORLD_WRITE	All users have permission to open the file for writing. This permission grants any user the right to replace the file. If this permission is set for a directory, this grants any user the right to create and delete files.
FILE_WORLD_EXECUTE	All users have permission to execute the contents of the file. If this permission is set for a directory, this may also grant all users the right to open that directory and search for files in that directory.

Return Value

If the method succeeds, the return value is a result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the SITE CHMOD command to set the permissions for the file. This command is typically only supported on servers that are hosted on UNIX based systems. If the command is not supported, an error will be returned.

Users who are familiar with the UNIX operating system will recognize the **chmod** command used to change the file permissions. However, it should be noted that the numeric value used as an argument to the command is in octal, not decimal. For example, issuing the command **chmod 644 filename.txt** on a UNIX based system will make the file readable and writable by the owner, and readable by other users in the owner's group as well as all other users. The value 644 is an octal value, which is equivalent to the decimal value 420. If you were to mistakenly specify 644 as the value for the *dwPermissions* parameter, rather than the decimal value of 420, the permissions on the file would be incorrect. It is strongly recommended that you use the pre-defined constants to prevent this sort of error.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFilePermissions](#), [GetFileStatus](#)

CFtpClient::SetFileStructure Method

```
INT SetFileStructure(  
    UINT nType  
);
```

The **SetFileStructure** method sets the default file structure for the current client session, which indicates what type of file is being opened or created on the server.

Parameters

nType

Specifies the default type of file structure being opened or created on the server. This parameter can be one of the following values.

Value	Description
FILE_STRUCT_NONE	The file has no inherent structure and is considered to be a stream of bytes. This is the default structure for file transfers.
FILE_STRUCT_RECORD	The file uses a record structure. This file structure is currently not supported.
FILE_STRUCT_PAGE	The file uses a page structure. This file structure is currently not supported.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The file structure should be set before a file is opened or created on the server. Once the file type is set, it is in effect for all files that are subsequently opened or created.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** csftpv11.lib
- Unicode:** Implemented as Unicode and ANSI versions

See Also

[OpenFile](#), [SetFileMode](#), [SetFileType](#), [SetPassiveMode](#)

CFtpClient::SetFileTime Method

```
INT SetFileTime(  
    LPCTSTR lpszFileName,  
    LPSYSTEMTIME lpFileTime  
);
```

The **SetFileTime** method sets the modification time for the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file.

lpFileTime

Points to a [SYSTEMTIME](#) structure that specifies the new modification time for the remote file.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SetFileTime** method will change the modification time of a file on the server. The values specified in the SYSTEMTIME structure are expected to represent UTC time, not time adjusted for the local system's timezone. If the values do represent the local time, it must be converted to UTC time prior to calling this method. To populate the SYSTEMTIME structure with the current time, use the **GetSystemTime** method.

When connected to an FTP server, this method uses the MDTM command to set the modification time for the specified file. Not all servers implement this command, in which case the method call will fail. Note that some servers only support the MDTM command to return, but not change, the file modification time.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetFileStatus](#), [GetFileTime](#), [OpenDirectory](#)

CFtpClient::SetFileType Method

```
INT SetFileType(  
    UINT nFileType  
);
```

The **SetFileType** method sets the default file type for the current client session, which indicates what type of file is being opened or created on the server.

Parameters

hClient

Handle to the client session.

nFileType

Specifies the default type of file being opened or created on the server. This parameter can be one of the following values.

Value	Description
FILE_TYPE_AUTO	The file type should be automatically determined based on the file name extension. If the file extension is unknown, the file type should be determined based on the contents of the file. The library has an internal list of common text file extensions, and additional file extensions can be registered using the FtpRegisterFileType function.
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
FILE_TYPE_EBCDIC	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server. Not all servers support this file type. It is recommended that you only specify this type if you know that it is required by the server to transfer data correctly.
FILE_TYPE_IMAGE	The file is a binary file and no data conversion of any type is performed on the file. This is the default file type for most data files and executable programs. If the type of file cannot be automatically determined, it will always be considered a binary file. If this file type is specified when uploading or downloading text files, the native end-of-line character sequences will be preserved.
FILE_TYPE_LOCAL	The file is a binary file that uses the local byte size for the server platform. On most servers, this file type is considered to be the same as FILE_TYPE_IMAGE. Not all servers support this file type. It is recommended that you only specify this type if you know that it is required by the server to transfer data correctly.

Return Value

If the function succeeds, the return value is the server result code. If the function fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The file type should be set before a file is opened or created on the server. Once the file type is set, it is in effect for all files that are subsequently opened or created. Some methods, such as **OpenDirectory** and **GetText**, will temporarily change the default file type to FILE_TYPE_ASCII and then restore the current file type when they return.

Calling this method has no practical effect when connected to an SFTP (SSH) server. They do not differentiate between text and binary files and the default file type will always be FILE_TYPE_IMAGE. If your application is uploading or downloading a text file, this difference between FTP and SFTP is important because the operating system that hosts the server may have different end-of-line character conventions than the client system. For example, if you download a text file from a UNIX system using SFTP, the end-of-line is indicated by a single linefeed (LF) character. However, on the Windows platform, the end-of-line is indicated by a carriage-return and linefeed sequence (CRLF).

The **GetFileType** method can be used to determine the current file type. To determine the transfer file type for a specific file, use the **GetAutoFileType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpClient::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the last error code for the current thread. This method is typically used to clear the last error by specifying a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the last error code for the current thread.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or FTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by using the **GetLastError** method. The use of **GetLastError** is optional; an application can call the method to determine the specific reason for a method failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[GetErrorString](#), [GetLastError](#), [ShowError](#)

CFtpClient::SetPassiveMode Method

```
INT SetPassiveMode(  
    BOOL bPassiveMode  
);
```

The **SetPassiveMode** method enables or disables passive mode file transfers for the specified client session.

Parameters

bPassiveMode

A boolean flag which specifies that the client should enter passive mode and establish all connections with the server to transfer data.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

By default, the File Transfer Protocol uses active mode transfers, whereby the data connection is established from the server back to the local client. However, this can introduce problems for a client application that is behind a proxy server, firewall or a router which uses Network Address Translation (NAT). Enabling passive mode transfers instructs the client to create an outbound connection from the local system to the server for the data connection, similarly to how the control connection is established.

Not all servers may support passive mode, in which case an error will be returned to the client when this method is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::SetPriority Method

```
INT SetPriority(  
    INT nPriority  
);
```

The **SetPriority** method specifies the priority for file transfers.

Parameters

nPriority

An integer value which specifies the new priority for file transfers. It may be one of the following values:

Value	Description
FTP_PRIORITY_NORMAL	The default priority which balances resource utilization and transfer speed. It is recommended that most applications use this priority.
FTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the transfer. It is typically used with worker threads running in the background when the amount of time required perform the transfer is not critical.
FTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the transfer and meters the bandwidth allocated for the transfer. This priority will increase the average amount of time required to complete a file transfer.
FTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the transfer, allocating more memory for internal buffering. It can be used when it is important to transfer the file quickly, and there are no other threads currently performing file transfers at the time.
FTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization while attempting to transfer the file as quickly as possible. If the file transfer is being performed in the main UI thread, this priority can cause the application to appear to become non-responsive. No events will be generated during the transfer.

Return Value

If the method succeeds, the return value is the previous file transfer priority. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SetPriority** method can be used to control the processor usage, memory and network bandwidth allocated for file transfers. The default priority balances resource utilization and transfer speed while ensuring that a single-threaded application remains responsive to the user. Lower priorities reduce the overall resource utilization at the expense of transfer speed. For example, if you create a worker thread to download a file in the background and want to ensure that it has a minimal impact on the

process, the `FTP_PRIORITY_BACKGROUND` value can be used.

Higher priority values increase the memory allocated for the transfers and increases processor utilization for the transfer. The `FTP_PRIORITY_CRITICAL` priority maximizes transfer speed at the expense of system resources. It is not recommended that you increase the file transfer priority unless you understand the implications of doing so and have thoroughly tested your application. If the file transfer is being performed in the main UI thread, increasing the priority may interfere with the normal processing of Windows messages and cause the application to appear to become non-responsive. It is also important to note that when the priority is set to `FTP_PRIORITY_CRITICAL`, normal progress events will not be generated during the transfer.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[GetPriority](#)

CFtpClient::SetTimeout Method

```
INT SetTimeout(  
    UINT nTimeout  
);
```

The **SetTimeout** method sets the number of seconds the client will wait for a response from the server. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

nTimeout

The number of seconds to wait for a blocking operation to complete.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpClient::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** function in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that function for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpClient::UploadFile Method

```
BOOL UploadFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    UINT nTimeout  
    DWORD dwOptions  
    LPFTPTRANSFERSTATUS lpStatus  
    FTPEVENTPROC lpEventProc  
    DWORD_PTR dwParam  
);
```

The **UploadFile** method uploads the specified file from the local system to the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be uploaded to the server. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the complete URL of the file that will be created or overwritten on the server. The URL must follow the conventions for the File Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response before failing the operation. A value of zero specifies that the default timeout period of sixty seconds will be used.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the client should attempt to establish the data connection with the server. When the client uploads or downloads a file, normally the server establishes a second connection back to the client which is used to transfer the file data. However, if the local system is behind a firewall or a NAT router, the server may not be able to create the data connection and the transfer will fail. By specifying this option, it forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the client should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this

	option is specified, it will also enable passive mode data transfers.
FTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol.
FTP_OPTION_SECURE_EXPLICIT	This option specifies the client should use the AUTH command to negotiate an explicit secure connection. Some servers may only require this when connecting to the server on ports other than 990.

lpStatus

A pointer to an FTPTRANSFERSTATUS structure which contains information about the status of the current file transfer. If this information is not required, a NULL pointer may be specified as the parameter.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **FtpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **UploadFile** method provides a convenient way for an application to upload a file in a single function call. Based on the connection information specified in the URL, it will connect to the server, authenticate the session, change the current working directory if necessary and then upload the file to the server. The URL must be complete, and specify either a standard or secure FTP scheme:

```
[ftp|ftps|sftp]://[username : password] @ hostname [:port] / [path / ...]
[filename] [;type=a|i]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. If a path is specified as part of the URL, then function will attempt to change the current working directory. Note that the path in an FTP URL is relative to the home directory of the user account and is not an absolute path starting at the root directory on the server. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "ftp" scheme is used and the FTP_OPTION_SECURE option is specified, that option will be ignored. To establish a secure connection, either the "ftps" or "sftp" scheme must be specified.

The optional "type" value at the end of the file name determines if the file should be uploaded as a text or binary file. A value of "a" specifies that the file should be uploaded as a text file. A value of "i" specifies that the file should be uploaded as a binary file. If the type is not explicitly specified, the file will be uploaded as a binary file.

The *lpStatus* parameter can be used by the application to determine the final status of the transfer, including the total number of bytes copied, the amount of time elapsed and other information related to the transfer process. If this information isn't needed, then this parameter may be specified as NULL.

The ***lpEventProc*** parameter specifies a pointer to a function which will be periodically called during the file transfer process. This can be used to check the status of the transfer by calling **GetTransferStatus** and then update the program's user interface. For example, the callback function could calculate the percentage for how much of the file has been transferred and then update a progress bar control. The ***dwParam*** parameter is used in conjunction with the event handler and specifies a user-defined value that is passed to the callback function. One common use in a C++ program is to pass the ***this*** pointer as the value, and then cast it back to an object pointer inside the callback function. If no event handler is required, then a NULL pointer can be specified as the value for ***lpEventProc*** and the ***dwParam*** parameter will be ignored.

The **UploadFile** method is designed to provide a simpler interface for uploading a file. However, complex connections such as those using a proxy server or a secure connection which uses a client certificate will require the program to establish the connection using **Connect** and then use **PutFile** to upload the file.

Example

```
CFtpClient ftpClient;
CString strLocalFile = _T("c:\\temp\\database.mdb");
CString strFileURL =
_T("ftp://update:secret@ftp.example.com/updates/database.mdb");

if (!ftpClient.UploadFile(strLocalFile, strFileURL))
{
    ftpClient.ShowError();
    return;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[FtpEventProc](#), [DownloadFile](#), [GetTransferStatus](#), [PutFile](#), [FTPTRANSFERSTATUS](#)

ValidateHostName Method

```
BOOL ValidateHostName(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);
```

```
BOOL ValidateHostName(  
    LPCTSTR lpszHostName,  
    CString& strAddress  
);
```

The **ValidateHostName** method determines if the specified host name is valid and returns its IP address.

Parameters

lpszHostName

A pointer to a null terminated string which specifies the host name. The method will fail if this parameter is NULL or an empty string.

lpszAddress

A pointer to a string buffer which will contain the IP address of the host. If specified, this string must be large enough to store the complete IP address, including the terminating null character. If this parameter is NULL or the *nMaxLength* parameter is zero, it will be ignored and the IP address will not be returned. An alternate version of this method accepts a reference to a **CString** object if MFC or ATL is used with the project.

nMaxLength

An integer value that specifies the maximum number of characters which can be copied into the *lpszAddress* string buffer. The buffer must be large enough to store the complete address. Because this method can return either an IPv4 or IPv6 address, it is recommended the minimum length for the buffer to be 46 characters. If this parameter is zero, the *lpszAddress* parameter will be ignored.

Return Value

If the method succeeds, the host name is valid and the return value will be non-zero. If the method fails, the host name could not be resolved to an IP address and the return value will be zero. To get extended error information, call the **GetLastError** method.

Remarks

The **ValidateHostName** method provides a convenient way to determine if a host name is valid by attempting to resolve the name into an IP address. If the Unicode version of this method is used, any non-ASCII characters in the host name will be automatically encoded into a compatible format and then resolved to an IP address. If you are unsure if an internationalized domain name will be specified as the host name, it is recommended you use the Unicode version.

If the *lpszHostName* parameter specifies a valid IPv4 or IPv6 address string instead of a host name, this method will return a copy of that IP address in the buffer provided by the caller. This allows the method to be used in cases where a user may input either a host name or IP address.

If you wish to validate a complete FTP URL instead of a host name, use the **ValidateUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ConnectUrl](#), [ValidateUrl](#)

CFtpClient::ValidateUrl Method

```
BOOL ValidateUrl(  
    LPCTSTR lpszUrl  
);
```

The **ValidateUrl** method determines if a string represents a valid FTP URL.

Parameters

lpszUrl

A pointer to a string that specifies the URL to validate.

Return Value

If the specified URL is valid and the host name can be resolved to an IP address, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **FtpGetLastError**.

Remarks

The **ValidateUrl** method will check the value of a string to ensure that it represents a complete, valid URL using either a standard or secure FTP scheme. This method will not establish a connection with the server to verify that it exists, it will only attempt to resolve the host name to an IP address. If the remote host is specified as an IP address, this method will check to make sure that the address is formatted correctly. Note that if you wish to specify an IPv6 address, you must enclose the address in brackets.

To establish a connection with a server using a URL, use the **ConnectUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ConnectUrl](#), [DownloadFile](#), [UploadFile](#), [ValidateHostName](#)

CFtpClient::VerifyFile Method

```
BOOL VerifyFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions  
);
```

The **VerifyFile** method attempts to verify that the contents of a file on the local system are the same as the specified file on the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the name of file on the local system.

lpszRemoteFile

A pointer to a string that specifies the name of the file on the server.

dwOptions

Specifies the options that may be used when comparing the files. This parameter may be one or more of the following values:

Value	Description
FTP_VERIFY_DEFAULT	File verification should use the best option available based on the available server features. If the server supports the XMD5 command, the class will calculate an MD5 hash of the local file contents and compare the value with the file on the server. If the server does not support the XMD5 command, but it does support the XCRC command, the class will calculate a CRC32 checksum of the local file contents and compare the value with the file on the server. If the server does not support either the XMD5 or XCRC commands, the class will compare the size of the local and remote files.
FTP_VERIFY_SIZE	Files are verified by comparing the number of bytes of data in the local and remote files. This is the least reliable method, and should only be used if the server does not support either the XMD5 or XCRC commands.
FTP_VERIFY_CRC32	Files are verified by calculating a CRC32 checksum of the local file contents and comparing it with the value returned by the server in response to the XCRC command. This method should only be used if the server does not support the XMD5 command.
FTP_VERIFY_MD5	Files are verified by calculating an MD5 hash of the local file contents and comparing it with the value returned by the server in response to the XMD5 command. This is the preferred method for performing file verification.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **VerifyFile** method will attempt to verify that the contents of the local and remote files are identical using one of several methods, based on the features that the server supports. Preference will be given to the most reliable method available, using either an MD5 hash, a CRC32 checksum or comparing the size of the file, in that order.

It is not recommended that you use this method with text files because of the different end-of-line conventions used by different operating systems. For example, a text file on a Windows system uses a carriage-return and linefeed pair to indicate the end of a line of text. However, on a UNIX system, a single linefeed is used to indicate the end of a line. This can cause the **VerifyFile** method to indicate the files are not identical, even though the only difference is in the end-of-line characters that are used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DeleteFile](#), [GetFile](#), [PutFile](#)

CFtpClient::Write Method

```
INT Write(  
    LPBYTE lpBuffer,  
    INT cbBuffer  
);  
  
INT Write(  
    LPCTSTR lpszBuffer,  
    INT cbBuffer  
);
```

The **Write** method sends the specified number of bytes to the server.

Parameters

lpBuffer

The pointer to the buffer which contains the data that is to be sent to the server. In an alternate form of the method, the pointer is to a string.

cbBuffer

The number of bytes to send from the specified buffer. This value must be greater than zero, unless a pointer to a string is passed as the buffer argument. In that case, if the value is -1, all of the characters in the string, up to but not including the terminating null character, will be sent to the server.

Return Value

If the method succeeds, the return value is the number of bytes actually written. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The return value may be less than the number of bytes specified by the *cbBuffer* parameter. In this case, the data has been partially written and it is the responsibility of the client application to send the remaining data at some later point. For non-blocking clients, the client must wait for the next asynchronous notification message before it resumes sending data.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

File Transfer Protocol Data Structures

- FTPCLIENTQUOTA
- FTPFILESTATUS
- FTPFILESTATUSEX
- FTPTRANSFERSTATUS
- FTPTRANSFERSTATUSEX
- SECURITYCREDENTIALS
- SECURITYINFO
- SYSTEMTIME

FTPCLIENTQUOTA

The **FTPCLIENTQUOTA** structure provides information about the file quota for the current client session.

```
typedef struct _FTPCLIENTQUOTA
{
    DWORD    dwFileCount;
    DWORD    dwFileLimit;
    DWORD    dwDiskUsage;
    DWORD    dwDiskLimit;
} FTPCLIENTQUOTA, *LPFTPCLIENTQUOTA;
```

Members

dwFileCount

An unsigned integer value which specifies the number of files that the user has created. If file quotas have not been enabled for the current user, this value will be zero.

dwFileLimit

An unsigned integer value which specifies the maximum number of files that may be created by the user. If file quotas have not been enabled for the current user, this value will be zero.

dwDiskUsage

An unsigned integer value which specifies the number of bytes of disk storage that has been allocated by the current user. If file quotas have not been enabled for the current user, this value will be zero.

dwDiskLimit

An unsigned integer value which specifies the maximum number of bytes of disk storage that may be allocated by the current user. If file quotas have not been enabled for the current user, this value will be zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

FTPFILESTATUS

This structure is used by the **EnumFiles**, **GetFirstFile** and **GetNextFile** methods to return information about files on the server.

```
typedef struct _FTPFILESTATUS
{
    TCHAR          szFileName[FTP_MAXFILENAMELEN];
    TCHAR          szFileOwner[FTP_MAXOWNERNAMELEN];
    TCHAR          szFileGroup[FTP_MAXGROUPNAMELEN];
    BOOL           bIsDirectory;
    DWORD          dwFileSize;
    DWORD          dwFileLinks;
    DWORD          dwFileVersion;
    DWORD          dwFilePerms;
    SYSTEMTIME     stFileDate;
} FTPFILESTATUS, *LPFTPFILESTATUS;
```

Members

szFileName

A string buffer which contains the name of the file on the server.

szFileOwner

A string buffer which contains the name of the user that owns the file on the server. Note that not all server types support the concept of file ownership by a user. Some UNIX systems will not provide this information if an anonymous login was used. For the proprietary Sterling directory formats, the "mailbox" is stored in this member.

szFileGroup

A string buffer which contains the name of the group that owns the file on the server. Note that not all server types support the concept of file ownership by a group. For the proprietary Sterling directory formats, the "batch number" is stored in this member, with the character # prepended for the format FTP_DIRECTORY_STERLING_2.

bIsDirectory

A boolean flag which specifies if the file is actually a subdirectory.

dwFileSize

The size of the file in bytes on the server. Servers that return file information in an MS-DOS format will always set this value to zero if the file refers to a subdirectory. If the file is a text file, the file size on the server may be different than the size on the local host if different end-of-line character conventions are used. It should be noted that under VMS, the file size is reported in 512 byte blocks, so the size should be considered approximate on that platform.

dwFileLinks

The number of links to the file. Note that not all server types support the concept of file links, in which case this value will be zero.

dwFileVersion

The number of revisions made to the file. Note that not all server types support the concept of file versioning, in which case this value will be zero. Currently this value will only be non-zero for VMS platforms.

dwFilePerms

The permissions associated with the file. This value is actually a combination of bits that specify the

individual permissions for the file owner, group and world (all other users). For those familiar with UNIX, the file permissions are the same as those used by the `chmod` command. For the proprietary Sterling directory formats, a bit map representing the status codes and transfer protocol of the file is stored in this member.

stFileDate

A [SYSTEMTIME](#) structure which specifies the date that the file was created or last modified.

File Permissions

Value	Description
FILE_OWNER_READ	The owner has permission to open the file for reading. If the current user is the owner of the file, this grants the user the right to download the file to the local system.
FILE_OWNER_WRITE	The owner has permission to open the file for writing. If the current user is the owner of the file, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_OWNER_EXECUTE	The owner has permission to execute the contents of the file. The file is typically either a binary executable, script or batch file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_GROUP_READ	Users in the specified group have permission to open the file for reading. If the current user is in the same group as the file owner, this grants the user the right to download the file.
FILE_GROUP_WRITE	Users in the specified group have permission to open the file for writing. On some platforms, this may also imply permission to delete the file. If the current user is in the same group as the file owner, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_GROUP_EXECUTE	Users in the specified group have permission to execute the contents of the file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_WORLD_READ	All users have permission to open the file for reading. This permission grants any user the right to download the file to the local system.
FILE_WORLD_WRITE	All users have permission to open the file for writing. This permission grants any user the right to replace the file. If this permission is set for a directory, this grants any user the right to create and delete files.
FILE_WORLD_EXECUTE	All users have permission to execute the contents of the file. If this permission is set for a directory, this may also grant all users the right to open that directory and search for files in that directory.

Sterling Status Codes

Bits 0-25 correspond to letters of the alphabet, most of which have distinct meanings in the Sterling formats.

Letter code	Bit position	Hexadecimal value

A	0	1h
B	1	2h
C	2	4h
<i>n-th letter of alphabet</i>	n-1	2 to the (n-1) power
Z	25	2000000h

For the proprietary Sterling directory formats, bits 26-31 represent the transfer protocol associated with the file:

Protocol	Bit position	Hexadecimal value	Constant
TCP	26	4000000h	FTP_STERLING_STATUS_TCP
FTP	27	8000000h	FTP_STERLING_STATUS_FTP
BSC	28	10000000h	FTP_STERLING_STATUS_BSC
ASC	29	20000000h	FTP_STERLING_STATUS_ASC
FTS	30	40000000h	FTP_STERLING_STATUS_FTS
other	31	80000000h	FTP_STERLING_STATUS_OTHER

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

FTPFILESTATUSEX

This structure is used by the **EnumFiles**, **GetFirstFile** and **GetNextFile** methods to return information about files on the server. This structure is designed for use with extended functions that support files larger than 4GB.

```
typedef struct _FTPFILESTATUSEX
{
    TCHAR          szFileName[FTP_MAXFILENAMELEN];
    TCHAR          szFileOwner[FTP_MAXOWNERNAMELEN];
    TCHAR          szFileGroup[FTP_MAXGROUPNAMELEN];
    BOOL           bIsDirectory;
    ULARGE_INTEGER uiFileSize;
    DWORD          dwFileLinks;
    DWORD          dwFileVersion;
    DWORD          dwFilePerms;
    DWORD          dwFileFlags;
    SYSTEMTIME     stFileDate;
} FTPFILESTATUSEX, *LPFTPFILESTATUSEX;
```

Members

szFileName

A string buffer which contains the name of the file on the server.

szFileOwner

A string buffer which contains the name of the user that owns the file on the server. Note that not all server types support the concept of file ownership by a user. Some UNIX systems will not provide this information if an anonymous login was used. For the proprietary Sterling directory formats, the "mailbox" is stored in this member.

szFileGroup

A string buffer which contains the name of the group that owns the file on the server. Note that not all server types support the concept of file ownership by a group. For the proprietary Sterling directory formats, the "batch number" is stored in this member, with the character # prepended for the format FTP_DIRECTORY_STERLING_2.

bIsDirectory

A boolean flag which specifies if the file is actually a subdirectory.

uiFileSize

The size of the file in bytes on the server. Servers that return file information in an MS-DOS format will always set this value to zero if the file refers to a subdirectory. If the file is a text file, the file size on the server may be different than the size on the local host if different end-of-line character conventions are used. It should be noted that under VMS, the file size is reported in 512 byte blocks, so the size should be considered approximate on that platform.

dwFileLinks

The number of links to the file. Note that not all server types support the concept of file links, in which case this value will be zero.

dwFileVersion

The number of revisions made to the file. Note that not all server types support the concept of file versioning, in which case this value will be zero. Currently this value will only be non-zero for VMS platforms.

dwFilePerms

The permissions associated with the file. This value is actually a combination of bits that specify the individual permissions for the file owner, group and world (all other users). For those familiar with UNIX, the file permissions are the same as those used by the `chmod` command. For the proprietary Sterling directory formats, a bit map representing the status codes and transfer protocol of the file is stored in this member.

dwFileFlags

This structure member is reserved for future use.

stFileDate

A [SYSTEMTIME](#) structure which specifies the date that the file was created or last modified.

File Permissions

Value	Description
FILE_OWNER_READ	The owner has permission to open the file for reading. If the current user is the owner of the file, this grants the user the right to download the file to the local system.
FILE_OWNER_WRITE	The owner has permission to open the file for writing. If the current user is the owner of the file, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_OWNER_EXECUTE	The owner has permission to execute the contents of the file. The file is typically either a binary executable, script or batch file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_GROUP_READ	Users in the specified group have permission to open the file for reading. If the current user is in the same group as the file owner, this grants the user the right to download the file.
FILE_GROUP_WRITE	Users in the specified group have permission to open the file for writing. On some platforms, this may also imply permission to delete the file. If the current user is in the same group as the file owner, this grants the user the right to replace the file. If this permission is set for a directory, this grants the user the right to create and delete files.
FILE_GROUP_EXECUTE	Users in the specified group have permission to execute the contents of the file. If this permission is set for a directory, this may also grant the user the right to open that directory and search for files in that directory.
FILE_WORLD_READ	All users have permission to open the file for reading. This permission grants any user the right to download the file to the local system.
FILE_WORLD_WRITE	All users have permission to open the file for writing. This permission grants any user the right to replace the file. If this permission is set for a directory, this grants any user the right to create and delete files.
FILE_WORLD_EXECUTE	All users have permission to execute the contents of the file. If this permission is set for a directory, this may also grant all users the right to open that directory and search for files in that directory.

Sterling Status Codes

Bits 0-25 correspond to letters of the alphabet, most of which have distinct meanings in the Sterling formats.

Letter code	Bit position	Hexadecimal value
A	0	1h
B	1	2h
C	2	4h
<i>n-th letter of alphabet</i>	n-1	2 to the (n-1) power
Z	25	2000000h

For the proprietary Sterling directory formats, bits 26-31 represent the transfer protocol associated with the file:

Protocol	Bit position	Hexadecimal value	Constant
TCP	26	4000000h	FTP_STERLING_STATUS_TCP
FTP	27	8000000h	FTP_STERLING_STATUS_FTP
BSC	28	10000000h	FTP_STERLING_STATUS_BSC
ASC	29	20000000h	FTP_STERLING_STATUS_ASC
FTS	30	40000000h	FTP_STERLING_STATUS_FTS
other	31	80000000h	FTP_STERLING_STATUS_OTHER

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

FTPTRANSFERSTATUS

This structure is used by the **GetTransferStatus** method to return information about a file transfer in progress.

```
typedef struct _FTPTRANSFERSTATUS
{
    DWORD    dwBytesTotal;
    DWORD    dwBytesCopied;
    DWORD    dwBytesPerSecond;
    DWORD    dwTimeElapsed;
    DWORD    dwTimeEstimated;
    TCHAR    szLocalFile[FTP_MAXFILENAMELEN];
    TCHAR    szRemoteFile[FTP_MAXFILENAMELEN];
} FTPTRANSFERSTATUS, *LPFTPTRANSFERSTATUS;
```

Members

dwBytesTotal

The total number of bytes that will be transferred. If the file is being copied from the server to the local host, this is the size of the remote file. If the file is being copied from the local host to the server, it is the size of the local file. If the file size cannot be determined, this value will be zero.

dwBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the file transfer is completed. This is based on the average number of bytes transferred per second.

szLocalFile

A pointer to a string which specifies the local file that is being copied to or from the server.

szRemoteFile

A pointer to a string which specifies the remote file that is being copied to or from the local system.

Remarks

If the option `FTP_OPTION_HIRES_TIMER` has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small files over a fast network connection.

If you are uploading or downloading large files which exceed 4GB, you should use the **FTPTRANSFERSTATUSEX** structure which uses 64-bit integers for the file size.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

FTPTRANSFERSTATUSEX

This structure is used by the **GetTransferStatus** method to return information about a file transfer in progress. This structure is designed for use with extended functions that support files larger than 4GB.

```
typedef struct _FTPTRANSFERSTATUSEX
{
    ULARGE_INTEGER dwBytesTotal;
    ULARGE_INTEGER dwBytesCopied;
    DWORD          dwBytesPerSecond;
    DWORD          dwTimeElapsed;
    DWORD          dwTimeEstimated;
    DWORD          dwReserved;
    TCHAR          szLocalFile[FTP_MAXFILENAMELEN];
    TCHAR          szRemoteFile[FTP_MAXFILENAMELEN];
} FTPTRANSFERSTATUSEX, *LPFTPTRANSFERSTATUSEX;
```

Members

uiBytesTotal

The total number of bytes that will be transferred. If the file is being copied from the server to the local host, this is the size of the remote file. If the file is being copied from the local host to the server, it is the size of the local file. If the file size cannot be determined, this value will be zero.

uiBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the file transfer is completed. This is based on the average number of bytes transferred per second.

dwReserved

This structure member is reserved for future use.

szLocalFile

A pointer to a string which specifies the local file that is being copied to or from the server.

szRemoteFile

A pointer to a string which specifies the remote file that is being copied to or from the local system.

Remarks

If the option `FTP_OPTION_HIRES_TIMER` has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small files over a fast network connection.

SECURITYCREDENTIALS

The **SECURITYCREDENTIALS** structure specifies the information needed by the library to specify additional security credentials, such as a client certificate or private key, when establishing a secure connection.

```
typedef struct _SECURITYCREDENTIALS
{
    DWORD    dwSize;
    DWORD    dwProtocol;
    DWORD    dwOptions;
    DWORD    dwReserved;
    LPCTSTR  lpszHostName;
    LPCTSTR  lpszUserName;
    LPCTSTR  lpszPassword;
    LPCTSTR  lpszCertStore;
    LPCTSTR  lpszCertName;
    LPCTSTR  lpszKeyFile;
} SECURITYCREDENTIALS, *LPSECURITYCREDENTIALS;
```

Members

dwSize

Size of this structure. If the structure is being allocated dynamically, this member must be set to the size of the structure and all other unused structure members must be initialized to a value of zero or NULL.

dwProtocol

A bitmask of supported security protocols. The value of this structure member is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.

SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.
SECURITY_PROTOCOL_SSH2	The Secure Shell 2.0 protocol should be used when establishing the connection. This is the default version of the protocol that is supported by most SSH servers.

dwOptions

A value which specifies one or options. This value should always be zero for connections using SSH. This member is constructed by using a bitwise operator with any of the following values:

Value	Description
CREDENTIAL_STORE_CURRENT_USER	The library will attempt to open a store for the current user using the certificate store name provided in this structure. If no options are specified, then this is the default behavior.
CREDENTIAL_STORE_LOCAL_MACHINE	The library will attempt to open a local machine store using the certificate store name provided in this structure. If this option is specified, the library will always search for a local machine store before searching for the store by that name for the current user.
CREDENTIAL_STORE_FILENAME	The certificate store name is a file that contains the certificate and private key that will be used.

dwReserved

This structure member is reserved for future use and should always be initialized to zero.

lpszHostName

A pointer to a null terminated string which specifies the hostname that will be used when validating the server certificate. If this member is NULL, then the server certificate will be validated against the

hostname used to establish the connection.

lpszUserName

A pointer to a null terminated string which identifies the owner of client certificate. Currently this member is not used by the library and should always be initialized as a NULL pointer.

lpszPassword

A pointer to a null terminated string which specifies the password needed to access the certificate. Currently this member is only used if the CREDENTIAL_STORE_FILENAME option has been specified. If there is no password associated with the certificate, then this member should be initialized as a NULL pointer.

lpszCertStore

A pointer to a null terminated string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The library will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the library will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the library will return an error indicating that the certificate could not be found. If the SECURITY_PROTOCOL_SSH protocol has been specified, this member should be NULL.

lpszKeyFile

A pointer to a null terminated string which specifies the name of the file which contains the private key required to establish the connection. This member is only used for SFTP (SSH) connections and should always be NULL when establishing a secure connection using FTPS (FTP+TLS). If the member is NULL, then no private key is used. The private key file must be in the standard PEM format defined in RFC 1422. Both the standard RSA private key format and the proprietary OpenSSH format are supported.

Remarks

A client application only needs to create this structure if the server requires that the client provide a certificate as part of the process of negotiating the secure session. If a certificate is required, note that it must have a private key associated with it. Attempting to use a certificate that does not have a private key will result in an error during the connection process indicating that the client credentials could not be established.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user, or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *dwOptions* member should be set to CREDENTIAL_STORE_FILENAME and the *lpszCertStore* member should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. Note that if a password was specified when the certificate file was created, it must be provided in the *lpszPassword* member or the library will be unable to access the certificate.

Note that the *lpszUserName* and *lpszPassword* members are values which are used to access the certificate store or private key file. They are not the credentials which are used when establishing the connection with the remote host or authenticating the client session.

The *lpszKeyFile* path can use environment variables enclosed in percent symbols, and the path to the private key file will be normalized. It is recommended you always use an absolute path to the private key file. If you do not include a path, it will use the current working directory for the process. This can produce inconsistent results with multithreaded applications because the current working directory for a process is a global value and it can be changed by any thread at any time.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

    SYSTEMTIME    stCertExpires;
    LPCTSTR       lpszCertIssuer;
    LPCTSTR       lpszCertSubject;
    LPCTSTR       lpszFingerprint;
} SECURITYINFO, *LPSECURITYINFO;
```

Members

dwSize

Specifies the size of the data structure. This member must always be initialized to the size of the structure in bytes prior to passing the address of this structure to the function. If this member is not initialized, an error will be returned indicating that an invalid parameter has been passed to the function.

dwProtocol

A numeric value which specifies the security protocol selected when establishing the connection.

Value	Description
SECURITY_PROTOCOL_NONE	The connection is not secure. This value indicates a standard connection was established and all other structure members will have a value of zero.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol was selected when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol was selected when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.

SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol was selected when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol was selected when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.
SECURITY_PROTOCOL_SSH2	The Secure Shell 2.0 protocol was selected. This protocol will only be used when connecting to an SSH server and is not supported with any other application protocol. Version 1.0 of the protocol is no longer considered secure and is not supported.

dwCipher

A numeric value which specifies the cipher that was selected when establishing the secure connection.

Value	Description
SECURITY_CIPHER_AES	The Advanced Encryption Standard cipher is a fixed block size cipher which use a key size of 128, 192 or 256 bits.
SECURITY_CIPHER_DES	The Data Encryption Standard block cipher was selected. This is a fixed key length cipher, using 56-bit keys.
SECURITY_CIPHER_DES3	The Triple DES block cipher was selected. This cipher encrypts the data three times using different keys, effectively providing a 168-bit length key.
SECURITY_CIPHER_DESX	A variant of the DES block cipher which XORs an extra 64-bits of the key before and after the plaintext has been encrypted, increasing the key size to 184 bits.
SECURITY_CIPHER_RC4	The RC4 stream cipher was selected. This is a variable key length cipher which supports keys between 40 and 128 bits, in 8-bit increments.
SECURITY_CIPHER_RC5	The RC5 block cipher was selected. This is a variable key length cipher which supports keys up to 2040 bits, in 8-bit increments.

dwCipherStrength

A numeric value which specifies the strength (the length of the cipher key in bits) of the cipher that was selected. Typically this value will be 128 or 256. 40-bit and 56-bit key lengths are considered weak encryption, and subject to brute force attacks. 128-bit and 256-bit key lengths are considered to be secure, and are the recommended key length for secure communications.

dwHash

A numeric value which specifies the hash algorithm which was selected.

Value	Description
-------	-------------

SECURITY_HASH_MD5	The MD5 algorithm was selected. Its use has been deprecated and is no longer considered to be cryptographically secure.
SECURITY_HASH_SHA1	The SHA-1 algorithm was selected. Its use has been deprecated and is no longer considered to be cryptographically secure.
SECURITY_HASH_SHA256	The SHA-256 algorithm was selected.
SECURITY_HASH_SHA384	The SHA-384 algorithm was selected.
SECURITY_HASH_SHA512	The SHA-512 algorithm was selected.

dwHashStrength

A numeric value which specifies the strength (the length in bits) of the message digest that was selected.

dwKeyExchange

A numeric value which specifies the key exchange algorithm which was selected.

Value	Description
SECURITY_KEYEX_RSA	The RSA public key algorithm was selected.
SECURITY_KEYEX_KEA	The Key Exchange Algorithm (KEA) was selected. This is an improved version of the Diffie-Hellman public key algorithm.
SECURITY_KEYEX_DH	The Diffie-Hellman key exchange algorithm was selected.
SECURITY_KEYEX_ECDH	The Elliptic Curve Diffie-Hellman key exchange algorithm was selected. This is a variant of the Diffie-Hellman algorithm which uses elliptic curve cryptography.

dwCertStatus

A numeric value which specifies the status of the certificate returned by the secure server.

Value	Description
SECURITY_CERTIFICATE_VALID	The certificate is valid.
SECURITY_CERTIFICATE_NOMATCH	The certificate is valid, but the domain name does not match the common name in the certificate.
SECURITY_CERTIFICATE_EXPIRED	The certificate is valid, but has expired.
SECURITY_CERTIFICATE_REVOKED	The certificate has been revoked and is no longer valid.
SECURITY_CERTIFICATE_UNTRUSTED	The certificate or certificate authority is not trusted on the local system.
SECURITY_CERTIFICATE_INVALID	The certificate is invalid. This typically indicates that the internal structure of the certificate has been damaged.

stCertIssued

A structure which contains the date and time that the certificate was issued by the certificate authority. If the issue date cannot be determined for the certificate, the SYSTEMTIME structure members will have zero values. This member only has meaning for connections using the TLS

protocol.

stCertExpires

A structure which contains the date and time that the certificate expires. If the expiration date cannot be determined for the certificate, the SYSTEMTIME structure members will have zero values.

lpszCertIssuer

A pointer to a string which contains information about the organization that issued the certificate. This string consists of one or more comma-separated tokens. Each token consists of an identifier, followed by an equal sign and a value. If the certificate issuer could not be determined, this member may be NULL. This member only has meaning for connections using the TLS protocol.

lpszCertSubject

A pointer to a string which contains information about the organization that the certificate was issued to. This string consists of one or more comma-separated tokens. Each token consists of an identifier, followed by an equal sign and a value. If the certificate subject could not be determined, this member may be NULL. This member only has meaning for connections using the TLS protocol.

lpszFingerprint

A pointer to a string which contains a sequence of hexadecimal values that uniquely identify the server. This member may be NULL.

Remarks

The size of this structure is typically determined using the **sizeof** operator in C/C++ and most other languages have a similar method for obtaining the size of a data structure or user-defined type. It is important to note the size of this structure will be different on 32-bit and 64-bit platforms due to the difference in the length of the structure members which are pointers.

When evaluating structure members which are string pointers, such as ***lpszCertIssuer*** and ***lpszCertSubject***, you should always check to ensure their values are not NULL (zero) before attempting to dereference them. If those values are undefined, it is not guaranteed they will point to zero-length strings.

There are additional protocols and ciphers defined which are not listed above because they are considered insecure and are no longer supported. It is important to note that most servers will reject attempts to use unsupported protocols such as SSL 3.0 and will either abort the connection or issue an error message and then immediately disconnect.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

The **SYSTEMTIME** structure represents a date and time using individual members for the month, day, year, weekday, hour, minute, second, and millisecond.

```
typedef struct _SYSTEMTIME
{
    WORD wYear;
    WORD wMonth;
    WORD wDayOfWeek;
    WORD wDay;
    WORD wHour;
    WORD wMinute;
    WORD wSecond;
    WORD wMilliseconds;
} SYSTEMTIME, *LPSYSTEMTIME;
```

Members

wYear

Specifies the current year. The year value must be greater than 1601.

wMonth

Specifies the current month. January is 1, February is 2 and so on.

wDayOfWeek

Specifies the current day of the week. Sunday is 0, Monday is 1 and so on.

wDay

Specifies the current day of the month

wHour

Specifies the current hour.

wMinute

Specifies the current minute

wSecond

Specifies the current second.

wMilliseconds

Specifies the current millisecond.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: windows.h.

File Transfer Queue Class Library

Manage a queue which will perform file transfers in the background.

Reference

- [Class Methods](#)
- [Data Structures](#)
- [Error Codes](#)

Library Information

Class Name	CFtpQueue
File Name	CSFTPV11.DLL
Version	11.0.2218.1855
LibID	22D6A6CD-4877-4CB9-B223-7149A9040534
Import Library	CSFTPV11.LIB
Dependencies	None
Standards	RFC 959, RFC 1579, RFC 2228

Overview

The File Transfer Queue class library provides a high-level interface to uploading and downloading a collection of files. Queued file transfers are performed in a background worker thread, with optional event notifications to inform the application about the current state of the queue and the files being processed.

A file may be queued for upload or download, and both uploads and downloads may be included in the same queue. Multiple instances of this class may be created to transfer multiple files at the same time. This class supports the same options available to individual file transfers using the [CFtpClient](#) class.

This class supports active and passive mode file transfers, firewall compatibility options, proxy servers and secure file transfers using the standard TLS 1.2 and SFTP protocols. Secure file transfers support implicit and explicit TLS sessions, client certificates and up to 256-bit AES encryption.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This class is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

File Transfer Queue Class Methods

Class	Description
CFtpQueue	Constructor which initializes the current instance of the class
~CFtpQueue	Destructor which releases resources allocated by the class
Method	Description
AddFile	Add a file to the transfer queue
AttachHandle	Attach the specified client handle to this instance of the class
Cancel	Cancel the specified queued file transfer
Clear	Remove all files from the transfer queue
DetachHandle	Detach the handle for the current instance of this class
DisableTrace	Disable logging of socket function calls to the trace log
EnableTrace	Enable logging of socket function calls to a file
EnumFiles	Enumerate queued files based on the specified criteria
FindFile	Find a specific file in the queue
FtpEventProc	Callback function that processes events generated during queued transfers
GetClient	Return a handle to the active client session during a queued file transfer
GetCount	Return the number of files queued for transfer
GetErrorString	Return a description for the specified error code
GetFile	Return information about the specified file
GetFirstFile	Return information about the first file in the transfer queue
GetHandle	Return a handle for the queue
GetLastError	Return the last error code
GetNextFile	Return information about the next file in the transfer queue
GetStatus	Return the current status of the file transfer queue
GetTransferStatus	Return information about the file being currently transferred
IsEmpty	Determine if the current file transfer queue is empty
IsIdle	Determine if the queue manager is currently idle
IsInitialized	Determine if the class has been successfully initialized
RegisterFileType	Associate a file name extension with a specific file type
RemoveFile	Remove a file from the transfer queue
Reset	Reset the internal state of file transfers in the queue
Resume	Resume the transfer of files after queue processing has been paused
SetLastError	Set the last error code
ShowError	Display a message box with a description of the specified error

Start	Begin transferring files in the queue
Stop	Stop transferring files in the queue
Suspend	Pause the transfer of files in the queue
Wait	Wait for the transfer of all queued files to complete

CFtpQueue::CFtpQueue Method

```
CFtpQueue();  
  
CFtpQueue(  
    UINT nMaxFiles,  
    UINT nTimeout,  
    DWORD dwOptions  
);
```

The **CFtpQueue** constructor initializes the class library and validates the license key at runtime.

Parameters

nMaxFiles

An unsigned integer which specifies the maximum number of files which can be added to the queue. The constant INFINITE can be used to specify that there is no fixed limit to the number of files in the queue.

nTimeout

An unsigned integer which specifies the default timeout for all queued file transfers. If this value is zero, a reasonable default timeout period will be used. This timeout period is used when a file is added to the queue without providing a timeout period for that specific file transfer. If a timeout period is specified for a particular file, it will override this value.

dwOptions

An unsigned integer value which specifies one or more default options for all queued files. This parameter is constructed by using a bitwise operator and can be any of the options used with the **CFtpClient::Connect** method. If transfer options are specified for a particular file, it will override this value. The most common options are:

Value	Description
FTP_OPTION_DEFAULT	Default options should be used for queued file transfers. This is the same as specifying that all file transfers should use passive mode when establishing a data connection with the server. It is recommended most applications use passive mode to prevent potential compatibility issues with certain types of firewalls and routers which use Network Address Translation (NAT).
FTP_OPTION_PASSIVE	This option specifies queued transfers should attempt to establish the data connection with the server. If the local system is behind a firewall or a NAT router, the server may not be able to establish a data connection back to the client and the transfer will fail. This option forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies queued transfers should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs

	Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.
FTP_OPTION_SECURE	This option specifies queued file transfers should attempt to establish a secure connection with the server by default. This option is the same as specifying FTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.
FTP_OPTION_SECURE_IMPLICIT	This option specifies queued file transfers should attempt to immediately establish secure TLS connection with the server by default. This option is typically used when connecting to a server on port 990, which is the default port number used for FTPS.
FTP_OPTION_SECURE_EXPLICIT	This option specifies queued file transfers should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure connection. This option is typically used when connecting to the server on ports other than 990.
FTP_OPTION_SECURE_SHELL	This option specifies queued file transfers should use the Secure Shell (SSH) protocol to establish the connection by default. This option will automatically be selected if the connection is established using port 22, the default port for SSH.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

If the **nMaxFiles** parameter is INFINITE, memory will be dynamically allocated on the process heap with no limit to the number of files which can be queued. If there is a logic error which causes the application to recursively add files to the queue, or repeatedly queue the same file, this can result in virtual memory being exhausted for the process. You can avoid this by specifying a reasonable maximum queue size, which will cause the **AddFile** method to fail if that limit is exceeded.

When called without any parameters, the constructor will create a queue with no file limit, default options and a default timeout period. The memory allocated for the queue will be released when the class destructor is invoked.

The constructor calls the **FtpInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[~CFtpQueue](#), [IsInitialized](#), [CFtpClient::Connect](#)

CFtpQueue::~CFtpQueue

`~CFtpQueue();`

The **CFtpQueue** destructor releases resources allocated by the current instance of the **CFtpQueue** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CFtpQueue** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

CFtpQueue::AddFile Method

```
DWORD AddFile(  
    DWORD dwQueueMode,  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions,  
    UINT nFileType,  
    UINT nTimeout  
);
```

```
DWORD AddFile(  
    DWORD dwQueueMode,  
    LPCTSTR lpszHostName,  
    UINT nHostPort,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions,  
    UINT nFileType,  
    UINT nTimeout  
);
```

The **AddFile** method adds a new file to the queue with additional transfer options.

Parameters

dwQueueMode

An integer value which specifies if the file should be downloaded from the server or uploaded to the server. This parameter must be one of the following options and cannot have a value of zero.

Constant	Description
FTP_QUEUE_DOWNLOAD	The file should be queued for downloading from the server to the local system.
FTP_QUEUE_UPLOAD	The file should be queued for uploading from the local system to the server.

lpszHostName

A pointer to the name of the server to establish a connection with. This may be a fully-qualified domain name or an IP address. If this parameter is NULL or points to an empty string, the *lpszRemoteFile* parameter must specify a complete URL which identifies the server as well as the path to the remote file.

nHostPort

The port number which should be used when establishing the connection. A value of zero specifies that the default port number should be used. For standard connections, the default port number is 21. For secure connections, the default port number is 990. If this parameter is zero and a URL is specified with the *lpszRemoteFile* parameter, the port number included in the URL will be used as the default value.

lpszUserName

Points to a null terminated string which specifies the user name to be used to authenticate the connection. If this parameter is NULL or an empty string, then the login is considered to be

anonymous. Note that anonymous logins are not supported for secure connections using the SSH protocol.

lpszPassword

Points to a null terminated string which specifies the password to be used to authenticate the current client session. This parameter may be NULL or an empty string if no password is required for the specified user, or if no username has been specified.

lpszLocalFile

A pointer to a null terminated string which specifies the name of the local file to be queued for transfer. This parameter cannot be NULL or point to an empty string. If the file is being queued for an upload, the file must exist on the local system or the method will fail. If the file is being downloaded, it will be created or replaced on the local system.

lpszRemoteFile

A pointer to a null terminated string which specifies the name of the file on the server. If the file is being downloaded, the file must exist on the server or the transfer will fail. If the file is being uploaded, the file will be created or replaced on the server. This parameter may specify a complete URL. Note that any values you specify as arguments to this method will override the values specified in the URL. If you want to use a URL as the remote file name, the ***lpszHostName*** parameter should be NULL and the ***nHostPort*** parameter should be zero.

dwOptions

An unsigned integer value which specifies one or more options. This parameter is constructed by using a bitwise operator and can be any of the options used with the **FtpClient::Connect** method. If this value is zero, the default options for the queue will be used. The most common options are:

Value	Description
FTP_OPTION_PASSIVE	This option specifies the file transfer should attempt to establish the data connection with the server. If the local system is behind a firewall or a NAT router, the server may not be able to establish a data connection back to the client and the transfer will fail. This option forces the client to establish an outbound data connection with the server. It is recommended that applications use passive mode whenever possible.
FTP_OPTION_FIREWALL	This option specifies the file transfer should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.
FTP_OPTION_SECURE	This option specifies the file transfer should attempt to establish a secure connection with the server by default. This option is the same as specifying FTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.

FTP_OPTION_SECURE_IMPLICIT	This option specifies the file transfer should attempt to immediately establish secure TLS connection with the server by default. This option is typically used when connecting to a server on port 990, which is the default port number used for FTPS.
FTP_OPTION_SECURE_EXPLICIT	This option specifies the file transfer should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure connection. This option is typically used when connecting to the server on ports other than 990.
FTP_OPTION_SECURE_SHELL	This option specifies the file transfer should use the Secure Shell (SSH) protocol to establish the connection by default. This option will automatically be selected if the connection is established using port 22, the default port for SSH.

nFileType

An integer value which specifies the type of file being transferred. It can be one of the following values:

Value	Description
FILE_TYPE_AUTO	The file type should be automatically determined based on the file name extension. If the file extension is unknown, the file type should be determined based on the contents of the file. The library has an internal list of common text file extensions, and additional file extensions can be registered using the RegisterFileType method.
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
FILE_TYPE_EBCDIC	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server. Not all servers support this file type. It is recommended that you only specify this type if you know that it is required by the server to transfer data correctly.
FILE_TYPE_IMAGE	The file is a binary file and no data conversion of any type is performed on the file. This is the default file type for most data files and executable programs. If the type of file cannot be automatically determined, it will always be considered a binary file. If this file type is specified when uploading or downloading text files, the native end-of-line character sequences will be preserved.
FILE_TYPE_LOCAL	The file is a binary file that uses the local byte size for the server platform. On most servers, this file type is considered to be the same as FILE_TYPE_IMAGE. Not all servers support this file type. It is recommended that you only specify this type if you know that it is required by the server to transfer data correctly.

nTimeout

The number of seconds to wait for a response from the server before failing the file transfer. If this value is zero, the default timeout period for the queue will be used.

lpvReserved

A reserved parameter which should always be NULL.

Return Value

If the method succeeds, the return value is a unique identifier which corresponds to the queued file. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will add a file to the current transfer queue. If successful, the value returned is a unique integer which identifies that file in the queue. To obtain information about the queued file, you can call the **GetFile** method and provide this return value as the *dwFileId* parameter. To remove a file from the queue, use the **RemoveFile** method.

Files can only be added to the queue when in an idle or paused state. If you attempt to add a file to the queue while the queue manager is transferring files, the method will fail. To determine the current state of the queue, call the **GetStatus** method.

There are no fixed limits to the number of files which can be queued for transfer. To release the memory allocated for the queue, call the **Clear** method. To determine the current status of the queue, including how many file transfers have been queued and how many are pending completion, call the **GetStatus** method.

If the local file name includes environment variables enclosed in percentage (%) symbols, those values will automatically be expanded based on the environment variables defined for the current user using the **ExpandEnvironmentStrings** function in the Windows API. Note that environment variable names are not case-sensitive.

This method will not immediately begin the process of uploading or downloading the file. It will only add the transfer request to the current queue. The file transfers are managed by a background worker thread which is created when the **Start** method is called.

Example

```
// Create a new queue
CFtpQueue pQueue = new CFtpQueue();

if (!pQueue->IsInitialized())
    return;

// Add a file to the queue
DWORD dwFileId = pQueue->AddFile(
    FTP_QUEUE_DOWNLOAD,
    lpzHostName,
    FTP_PORT_DEFAULT,
    lpzUserName,
    lpzPassword,
    lpzLocalFile,
    lpzRemoteFile);

// Display information about the queued file
if (dwFileId != 0)
{
    FTPQUEUEDFILE queuedFile;
```

```

if (pQueue->GetFile(dwFileId, &queuedFile))
{
    switch (queuedFile.dwMode)
    {
        case FTP_QUEUE_DOWNLOAD:
            _tprintf(_T("%u: Download \"%s\" to \"%s\"\\n"),
                dwFileId,
                queuedFile.szRemoteFile,
                queuedFile.szLocalFile);
            break;

        case FTP_QUEUE_UPLOAD:
            _tprintf(_T("%u: Upload \"%s\" to \"%s\"\\n"),
                dwFileId,
                queuedFile.szLocalFile,
                queuedFile.szRemoteFile);
            break;
    }
}

// Start the queued file transfers and wait for it to complete
if (pQueue->Start())
{
    pQueue->Wait(INFINITE);
    pQueue->Stop();
}

// Remove all files from the queue
delete pQueue;

```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CFtpQueue](#), [~CFtpQueue](#), [FindFile](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#), [RemoveFile](#)

CFtpQueue::AttachHandle Method

```
VOID AttachHandle(  
    HQUEUE hQueue  
);
```

The **AttachHandle** method attaches the specified queue handle to the current instance of the class.

Parameters

hQueue

A handle to the queue.

Return Value

None.

Remarks

This method is used to attach a queue handle created outside of the class using the SocketTools API. Once the handle is attached to the class, the other class member functions may be used with that queue.

If a handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous queue from being destroyed, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hQueue* parameter is presumed to be a valid queue handle and no checks are performed to ensure that the handle is valid. Specifying an invalid queue handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[DetachHandle](#), [GetHandle](#)

CFTPQueue::Cancel Method

```
BOOL Cancel(  
    DWORD dwFileId  
);
```

The **Cancel** method cancels the specified file transfer.

Parameters

dwFileId

An optional unsigned integer value which uniquely identifies the file in the queue. If this parameter is omitted or the value is zero, the method will cancel the current file transfer in progress. If queue transfers have been suspended, this parameter cannot be zero.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

When this method is called, the queued file transfer may not immediately stop. An internal flag is set which causes the file transfer to exit with an error and the queue manager will begin processing the next file in the queue. If the queue is in an idle state, this method will fail.

It is permitted to call the **Cancel** method from within a queue event handler to cancel the current file transfer. In this case, the *dwFileId* parameter should be zero. If you specify a file which has not been transferred, it will be flagged as canceled and skipped by the queue manager when processing the queue. If you specify a file which has already been processed, this method will fail.

A canceled file transfer is also considered a failed transfer. When you call **GetStatus** after a queued file transfer is canceled, the *dwFailedFiles* member of the [FTPQUEUESTATUS](#) structure will be incremented to reflect this change. You can determine the status of an individual file transfer by calling the **GetFile** method and checking the value of the *dwQueueFlags* member of the [FTPQUEUEFILE](#) structure.

The **Reset** method can be used to reset the state of previously canceled transfers.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

CFtpQueue::Clear Method

BOOL Clear();

The **Clear** method removes all files from the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method can only be called when the queue is in an idle state. An error will be returned if the method is called while the queue manager is paused or actively transferring files in the queue. To determine the current state of the queue, call the **GetStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

CFtpQueue::DetachHandle Method

```
HQUEUE DetachHandle();
```

The **DetachHandle** method detaches the queue handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the queue handle associated with the current instance of the class object. If an error occurs, the value INVALID_QUEUE will be returned.

Remarks

This method is used to detach a queue handle created by the class for use with the SocketTools API. Once the handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpQueue::DisableTrace Method

```
BOOL DisableTrace();
```

The **DisableTrace** method disables the logging of socket function calls to the trace log.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, a value of zero is returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[EnableTrace](#)

CFtpQueue::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of network function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads. This option is always selected for the CFtpQueue class.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the server.

Trace method logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DisableTrace](#)

CFtpQueue::EnumFiles Method

```
LONG EnumFiles(  
    LPCTSTR lpszFileMask,  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles,  
    LPDWORD lpFileList,  
    LONG nMaxFiles  
);
```

The **EnumFiles** method returns a list of files in the current transfer queue.

Parameters

lpszFileMask

A pointer to a null terminated string which specifies a file name which can include wildcards. Only those files which match this value will be enumerated. The character '?' will match against any single character, and '*' will match any number of characters. If this parameter is NULL or points to an empty string, all eligible files in the queue will be matched.

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. Only those files which match the queue mode will be enumerated. This is a bitmask which may be one or more of the following values:

Constant	Description
FTP_QUEUE_ALL	Match the file name to all files in the queue.
FTP_QUEUE_DOWNLOAD	Match file names which are queued for download.
FTP_QUEUE_UPLOAD	Match file names which are queued for upload.
FTP_QUEUE_LOCAL	Match against the local file name instead of the remote file name.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the enumeration. If this value is zero, no files will be excluded; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_QUEUE_FLAG_NONE	No files should be excluded.
FTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
FTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
FTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of being

lpFileList

A pointer to an array of unsigned integer values which will contain the unique file identifiers for each matching file in the queue. This parameter must specify an array large enough to store all of the file identifiers, otherwise the method will fail with a **ST_ERROR_BUFFER_TOO_SMALL** error. If this parameter is NULL, the method will return the number of matching files.

nMaxFiles

An integer value which specifies the maximum number of file identifiers which can be copied into the *lpFileList* array. If the *lpFileList* parameter is not NULL, this value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of matching files. If the queue is empty or there are no matching files, this method will return zero. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method populates an array of unique file identifiers which can be used to obtain information about the files in the current queue. The values returned in the *lpFileList* array can be used in conjunction with the **GetFile** method. This provides an alternative to using the **GetFirstFile** and **GetNextFile** methods.

The application should not make any assumptions about the value of the file identifiers returned by this method. They should be considered opaque values which are only guaranteed to uniquely identify a file in the transfer queue. In particular, there is no guarantee that the file identifiers will be sequential and they should not be used as index values into an array.

Example

```
// Get the total number of files in the queue
LONG nFiles = pQueue->GetCount();

// Display information about the queued files
if (nFiles > 0)
{
    DWORD *pdwFileList = new DWORD[nFiles];
    nFiles = pQueue->EnumFiles(NULL, FTP_QUEUE_ALL, FTP_QUEUE_FLAG_NONE,
pdwFileList, nFiles);

    for (LONG nIndex = 0; nIndex < nFiles; nIndex++)
    {
        FTPQUEUEDFILE queuedFile;

        if (pQueue->GetFile(pdwFileList[nIndex], &queuedFile) == FALSE)
            break;

        switch (queuedFile.dwMode)
        {
        case FTP_QUEUE_DOWNLOAD:
            _tprintf(_T("%u: Download \"%s\" to \"%s\"\\n"),
                queuedFile.dwFileId,
                queuedFile.szRemoteFile,
                queuedFile.szLocalFile);
            break;

        case FTP_QUEUE_UPLOAD:
```

```
        _tprintf(_T("%u: Upload \"%s\" to \"%s\"\\n"),
                queuedFile.dwFileId,
                queuedFile.szLocalFile,
                queuedFile.szRemoteFile);
        break;
    }
}

delete pdwFileList;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AddFile](#), [FindFile](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#), [RemoveFile](#)

CFtpQueue::FindFile Method

```
DWORD FindFile(  
    LPCTSTR lpszFileName,  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles  
);
```

The **FindFile** method finds a file in the transfer queue which matches the search criteria.

Parameters

lpszFileName

A pointer to a null terminated string which specifies the name of the file to search for. The string may contain the wildcard character '?' to match against any single character, and '*' will match any number of characters. This parameter cannot be NULL or point to an empty string.

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. This is a bitmask which may be one or more of the following values:

Constant	Description
FTP_QUEUE_ALL	Match the file name to all files in the queue.
FTP_QUEUE_DOWNLOAD	Match file names which are queued for download.
FTP_QUEUE_UPLOAD	Match file names which are queued for upload.
FTP_QUEUE_LOCAL	Match against the local file name instead of the remote file name.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the search. If this value is zero, no files will be excluded from the search; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_QUEUE_FLAG_NONE	No files should be excluded from the search.
FTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
FTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
FTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

Return Value

If the method succeeds, the return value is a unique identifier for the file. To obtain information about the file, call the **GetFile** method. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns a unique file identifier for the first file which matches the specified file name in the queue. If the *lpzFileName* parameter includes wildcard characters, this method will return the first file in the queue which matches the name. File name matches are not case-sensitive, even when matching against remote file names on servers which use case-sensitive naming, such as UNIX based servers.

To perform more complex searches based on the file name, or to find multiple files, you can use the **GetFirstFile** and **GetNextFile** methods to iterate through all queued files.

Example

```
// Find a local file in the download queue
DWORD dwFileId = pQueue->FindFile(lpzFileName,
                                   FTP_QUEUE_DOWNLOAD | FTP_QUEUE_LOCAL,
                                   FTP_QUEUE_FLAG_NONE);

// Display information about the queued file
if (dwFileId != 0)
{
    FTPQUEUEDFILE queuedFile;

    if (pQueue->GetFile(dwFileId, &queuedFile))
    {
        switch (queuedFile.dwMode)
        {
            case FTP_QUEUE_DOWNLOAD:
                _tprintf(_T("%u: Download \"%s\" to \"%s\"\n"),
                        dwFileId,
                        queuedFile.szRemoteFile,
                        queuedFile.szLocalFile);
                break;

            case FTP_QUEUE_UPLOAD:
                _tprintf(_T("%u: Upload \"%s\" to \"%s\"\n"),
                        dwFileId,
                        queuedFile.szLocalFile,
                        queuedFile.szRemoteFile);
                break;
        }
    }
}
```

CFtpQueue::GetClient Method

HCLIENT GetClient();

The **GetClient** method returns a handle to the current client session.

Parameters

None.

Return Value

If the method succeeds, the return value is a handle to a client session. If the method fails, it will return **INVALID_CLIENT**. To get extended error information, call **GetLastError**.

Remarks

The **GetClient** method returns the handle to a client session which may be used with other methods. A valid handle will only be returned if the queue manager is currently uploading or downloading a file. If the queue is active but there are no file transfers in progress at the time this method is called, it will fail and set the last error code to **ST_ERROR_NO_QUEUED_TRANSFER**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

CFtpQueue::GetCount Method

LONG GetCount();

The **GetCount** method returns the total number of files which have been queued for transfer.

Parameters

None.

Return Value

If the method succeeds, the return value is the number of files in the queue. If the method fails, it will return FTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

See Also

[CFtpQueue](#), [~CFtpQueue](#), [EnumFiles](#), [GetStatus](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#)

CFtpQueue::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT cbDescription  
);  
  
INT GetErrorString(  
    DWORD dwErrorCode,  
    CString& strDescription  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length. An alternate form of the method accepts a **CString** variable which will contain the error description.

cbDescription

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is zero, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLastError](#), [SetLastError](#), [ShowError](#)

CFTPQueue::GetFile Method

```
BOOL GetFile(
    LPCTSTR lpszFileName,
    LPFTPQUEUEDFILE lpFileInfo
);

BOOL GetFile(
    DWORD dwFileId,
    LPFTPQUEUEDFILE lpFileInfo
);
```

The **GetFile** method returns information about the specified file in the transfer queue.

Parameters

lpszFileName

A pointer to a null terminated string which specifies the name of the file in the queue. The name should always be the name of the remote file to search for.

dwFileId

An unsigned integer value which uniquely identifies the file in the queue. This value cannot be zero.

lpFileInfo

A pointer to a [FTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the file identifier is not valid or the file has been removed from the queue, the return value is zero. To get extended error information, call **FtpGetLastError**.

Remarks

The file identifier can be obtained by several different methods, including **EnumFiles** and **GetStatus**, which provides information about the current file being processed in the queue. Do not make any assumptions about the value of the identifier. Although the value is guaranteed to be unique for the specified queue, it is not guaranteed that file identifiers will be assigned in sequential order.

If you call the version of this method which accepts a file name, it will use the **FindFile** method to obtain the file ID for the first file name which matches a remote file in the queue. This approach is only recommended if you know that the queued file names will be unique.

Example

```
// Get the number of files in the queue
LONG nFiles = pQueue->GetCount();

// Display information about the queued files
if (nFiles > 0)
{
    DWORD *pdwFileList = new DWORD[nFiles];

    nFiles = pQueue->EnumFiles(pdwFileList, nFiles);

    for (LONG nIndex = 0; nIndex < nFiles; nIndex++)
    {
        FTPQUEUEDFILE queuedFile;
```

```

    if (pQueue->GetFile(pdwFileList[nIndex], &queuedFile) == FALSE)
        break;

    switch (queuedFile.dwMode)
    {
    case FTP_QUEUE_DOWNLOAD:
        _tprintf(_T("%u: Download \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szRemoteFile,
            queuedFile.szLocalFile);
        break;

    case FTP_QUEUE_UPLOAD:
        _tprintf(_T("%u: Upload \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szLocalFile,
            queuedFile.szRemoteFile);
        break;
    }
}

delete pdwFileList;
}

```

Requirements

CFtpQueue::GetFirstFile Method

```
DWORD GetFirstFile(  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles,  
    LPFTPQUEUEDFILE lpFileInfo  
);
```

The **FtpGetFirstFile** method returns information about the first file in the transfer queue.

Parameters

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. It may be one of the following values:

Constant	Description
FTP_QUEUE_ALL	Return information about all files in the queue.
FTP_QUEUE_DOWNLOAD	Return information for files which are queued for download.
FTP_QUEUE_UPLOAD	Return information for files which are queued for upload.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the search. If this value is zero, no files will be excluded from the search; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
FTP_QUEUE_FLAG_NONE	No files should be excluded.
FTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
FTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
FTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

lpFileInfo

A pointer to a [FTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is an unsigned integer with a non-zero value which uniquely identifies the file in the queue. If there are no queued files which match the specified parameters, or

the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns information about the first file in the current transfer queue. It is used in conjunction with the **GetNextFile** method to obtain information about all queued files.

Example

```
// List all files in a file transfer queue
FTPQUEUEDFILE queuedFile;
DWORD dwFileId;

dwFileId = pQueue->GetFirstFile(FTP_QUEUE_ALL, FTP_QUEUE_FLAG_NONE, &queuedFile);

while (dwFileId != 0)
{
    switch (queuedFile.dwQueueMode)
    {
    case FTP_QUEUE_DOWNLOAD:
        _tprintf(_T("%u: download \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szRemoteFile,
            queuedFile.szLocalFile);
        break;

    case FTP_QUEUE_UPLOAD:
        _tprintf(_T("%u: upload \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szRemoteFile,
            queuedFile.szLocalFile);
        break;
    }

    dwFileId = pQueue->GetNextFile(&queuedFile);
}
```

Requirements

CFtpQueue::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or FTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[GetErrorString](#), [SetLastError](#), [ShowError](#)

CFtpQueue::GetNextFile Method

```
DWORD GetNextFile(  
    LPFTPQUEUEDFILE lpFileInfo  
);
```

The **GetNextFile** method returns information about the next file in the transfer queue.

Parameters

lpFileInfo

A pointer to a [FTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is an unsigned integer with a non-zero value which uniquely identifies the file in the queue. If there are no additional queued files which match the exclusion criteria specified with the call to **GetFirstFile**, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns information about the next file in the current transfer queue after an initial call to **GetFirstFile**. To obtain a list of all matching files in the queue, call this method repeatedly until it returns a value of zero. When information about the last file in the queue has been returned, the last error code will be set to **ST_ERROR_END_OF_QUEUE**.

Example

```
// List all files in a file transfer queue  
FTPQUEUEDFILE queuedFile;  
DWORD dwFileId;  
  
dwFileId = pQueue->GetFirstFile(FTP_QUEUE_ALL, FTP_QUEUE_FLAG_NONE, &queuedFile);  
  
while (dwFileId != 0)  
{  
    switch (queuedFile.dwQueueMode)  
    {  
        case FTP_QUEUE_DOWNLOAD:  
            _tprintf(_T("%u: download \"%s\" to \"%s\"\\n"),  
                    queuedFile.dwFileId,  
                    queuedFile.szRemoteFile,  
                    queuedFile.szLocalFile);  
            break;  
  
        case FTP_QUEUE_UPLOAD:  
            _tprintf(_T("%u: upload \"%s\" to \"%s\"\\n"),  
                    queuedFile.dwFileId,  
                    queuedFile.szRemoteFile,  
                    queuedFile.szLocalFile);  
            break;  
    }  
  
    dwFileId = pQueue->GetNextFile(&queuedFile);  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpQueue::GetStatus Method

```
INT GetStatus(  
    LPFTPQUEUESTATUS LpQueueStatus  
);
```

The **GetStatus** method returns information about the specified file in the transfer queue.

Parameters

LpQueueStatus
A pointer to a [FTPQUEUESTATUS](#) structure which will contain information about the current state of the file transfer queue. If this parameter is NULL, the method will ignore the parameter and only return the current status of the queue.

Return Value

If the method succeeds, the return value is the current queue status. If the method fails, the return value is FTP_ERROR. To get extended error information, call **FtpGetLastError**. The following status values may be returned:

Value	Description
FTP_QUEUE_STATUS_IDLE	The file transfer queue is idle and no files are being uploaded or downloaded. This state is returned before FtpStartQueue has been called or after FtpStopQueue has been called. The queue will also automatically enter an idle state after the last file transfer has completed and the queue manager thread exits.
FTP_QUEUE_STATUS_ACTIVE	The queue manager is active and files are currently being uploaded or downloaded.
FTP_QUEUE_STATUS_PAUSED	The queue manager is active although file transfers are currently paused. The queue enters this state after the FtpSuspendQueue method is called and resumes file transfers after the FtpResumeQueue method is called.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** cstdlib11.h
- Import Library:** csftpv11.lib

CFtpQueue::GetTransferStatus Method

```
INT GetTransferStatus(  
    LPFTPTRANSFERSTATUS LpStatus  
);  
  
INT GetTransferStatus(  
    LPFTPTRANSFERSTATUSEX LpStatus  
);
```

The **GetTransferStatus** method returns information about the current file transfer in progress.

Parameters

LpStatus

A pointer to an [FTPTRANSFERSTATUS](#) or [FTPTRANSFERSTATUSEX](#) structure which contains information about the status of the current file transfer.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is `FTP_ERROR`. To get extended error information, call **GetLastError**.

Remarks

The **GetTransferStatus** method returns information about the current file transfer, including the average number of bytes transferred per second and the estimated amount of time until the transfer completes. This method would typically be called from within a callback function in response to an `FTP_EVENT_PROGRESS` event notification.

The *dwBytesTotal* and *dwBytesCopied* members of the **FTPTRANSFERSTATUSEX** structure are declared as unsigned 64-bit integers rather than 32-bit integers. To obtain accurate file transfer information, this extended version of the structure should be used with files that are larger than 4GiB.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

Unicode: Implemented as Unicode and ANSI versions

CFtpQueue::IsEmpty Method

BOOL IsEmpty();

The **IsEmpty** method determines if the current queue is empty.

Parameters

None.

Return Value

If no files have been added to the queue, the return value is non-zero. If one or more files have been added to the queue, the method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[AddFile](#) [Clear](#) [GetFile](#), [IsIdle](#), [RemoveFile](#)

CFtpQueue::IsIdle Method

BOOL IsIdle();

The **IsIdle** method determines if the queue is idle.

Parameters

None.

Return Value

If the queue is idle and no files are being transferred, this method returns a non-zero value. If the queue manager is currently transferring files, the return value is zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

CFtpQueue::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

CFtpQueue::RegisterFileType Method

```
BOOL RegisterFileType(  
    LPCTSTR lpszExtension,  
    UINT nFileType  
);
```

The **RegisterFileType** method associates a file name extension with a specific file type.

Parameters

lpszExtension

A pointer to a null terminated string which specifies the file name extension. If this parameter is NULL or points to an empty string, the default file type will be changed for the client session.

nFileType

Specifies the type of file associated with the file extension. This parameter can be one of the following values.

Value	Description
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those servers which mark the end of a line with characters other than a carriage return and linefeed, it will be converted to the native client format. This is the file type used for directory listings.
FILE_TYPE_EBCDIC	The file is a text file using the EBCDIC character set. Local files will be converted to EBCDIC when sent to the server. Remote files will be converted to the native ASCII character set when retrieved from the server.
FILE_TYPE_IMAGE	The file is a binary image and no data conversion of any type is performed on the file. This is typically the default file type for data file transfers. If the type of file that is being transferred is unknown, this file type should always be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **RegisterFileType** method is used to associate specific file types with file name extensions. The class has an internal list of standard text file extensions which it automatically recognizes. This method can be used to extend or modify that global list. Registered file types are shared by all queues created by the application.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** csftpv11.lib
- Unicode:** Implemented as Unicode and ANSI versions

See Also

CFtpQueue::RemoveFile Method

```
BOOL RemoveFile(  
    DWORD dwFileId  
);  
  
BOOL RemoveFile(  
    LPCTSTR lpszFileName  
);
```

The **RemoveFile** method removes the specified file from the queue.

Parameters

dwFileId

An unsigned integer value which uniquely identifies the file in the queue. This value cannot be zero.

lpszFileName

A pointer to a null terminated string which specifies the name of the file to remove. If this version of the method is called, this parameter cannot be NULL or point to an empty string. The file name may include wildcard characters if you wish to remove multiple files. The character '?' will match against any single character, and '*' will match any number of characters.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **FtpGetLastError**.

Remarks

Files can only be removed from the queue when in an idle or paused state. If you attempt to remove a file while the queue manager is in the process of uploading or download files, the method will fail.

The file identifier can be obtained by several different methods, including **EnumFiles** and **GetStatus**, which provides information about the current file being processed in the queue. Do not make any assumptions about the value of the identifier. Although the value is guaranteed to be unique for the specified queue, it is not guaranteed that file identifiers will be assigned in sequential order.

If you call this method using a file name, the **EnumFiles** method will be used to enumerate all remote file names which match and remove them from the queue. File name matches are not case-sensitive, even when matching against file names on servers which use case-sensitive naming, such as UNIX based servers.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[AddFile](#) [Clear](#) [IsEmpty](#), [Reset](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#)

CFtpQueue::Reset Method

```
BOOL Reset(  
    DWORD dwOptions  
);
```

The **Reset** method resets the state of all file transfers in the current queue.

Parameters

dwOptions

An unsigned integer value which specifies which files should be reset in the queue. It may be one of the following values:

Value	Description
FTP_QUEUE_RESET_ALL	All files in the queue should be reset to their initial state.
FTP_QUEUE_RESET_COMPLETED	All files in the queue which have been successfully transferred will be reset to their initial state.
FTP_QUEUE_RESET_FAILED	All files in the queue which were not transferred will be reset to their initial state.
FTP_QUEUE_RESET_CANCELED	All files in the queue which were canceled will be reset to their initial state.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

When the **Start** method is called multiple times, it will not attempt to transfer files which have already been successfully copied, and it will not attempt to re-transfer files if the previous transfer failed. This method resets queued files back to their initial state, prior to when the queue manager attempted to perform the transfer. The most common use would be to call the method with the FTP_QUEUE_RESET_FAILED mode and then call **Start** to retry failed or canceled file transfers.

Because canceled file transfers are also considered failed transfers, specifying FTP_QUEUE_RESET_FAILED will reset queued files which either encountered an error during the transfer or were explicitly canceled by calling the **Cancel** method. The FTP_QUEUE_RESET_CANCELED option will only reset the state of queued file transfers which were canceled.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[AddFile](#), [Cancel](#), [Clear](#), [IsEmpty](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#), [Wait](#)

CFtpQueue::Resume Method

```
BOOL Resume();
```

The **Resume** method resumes transfers in the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method signals the queue manager to resume processing files in the transfer queue after the **Suspend** method has been called. This method will fail if the queue is in an idle (stopped) state, and will be ignored if the queue manager is already transferring files. The **GetStatus** method can be called to obtain the current status of the queue.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[Cancel](#), [Clear](#), [GetStatus](#), [Start](#), [Stop](#), [Suspend](#), [Wait](#)

CFtpQueue::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the last error code for the current thread. This method is typically used to clear the last error by specifying a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the last error code for the current thread.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Failure is typically indicated by a return value such as FALSE, NULL, INVALID_QUEUE or FTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by calling the **GetLastError** method. The use of **GetLastError** is optional; an application can use the method to determine the specific reason for a failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

[GetErrorString](#), [GetLastError](#), [ShowError](#)

CFtpQueue::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** function in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that function for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpQueue::Start Method

```
BOOL Start(  
    DWORD dwQueueMode,  
    FTPEVENTPROC lpEventProc,  
    DWORD_PTR dwParam  
);
```

The **Start** method begins transferring files in the queue.

Parameters

dwQueueMode

An unsigned integer which specifies which files in the queue should be transferred. It may be one of the following values:

Constant	Description
FTP_QUEUE_ALL	All files in the queue should be transferred.
FTP_QUEUE_DOWNLOAD	Transfer only those files which have been queued for download.
FTP_QUEUE_UPLOAD	Transfer only those files which have been queued for upload.

lpEventProc

Specifies the procedure-instance address of an application defined callback function. For more information about the callback method, see the description of the **FtpEventProc** callback method. If this parameter is NULL, there will be no callback notifications.

dwParam

A user-defined integer value that is passed to the callback method. If the application targets the x86 (32-bit) platform, this parameter must be a 32-bit unsigned integer. If the application targets the x64 (64-bit) platform, this parameter must be a 64-bit unsigned integer.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

Queued file transfers are performed asynchronously using a background worker thread. If you provide the address to an event callback function, that method will always be invoked in the context of the queue manager thread. You must ensure that any access to global or static variables are synchronized, otherwise the results may be unpredictable. It is recommended that you do not declare any static variables within the callback function itself and you should avoid calling any methods which could cause the thread to block. For example, you should not attempt to establish other network connections from within the event handler.

If your application has a graphical user interface, you should never attempt to directly modify a UI control from within the callback method. Controls should only be modified by the same UI thread that created their window. One common approach to address this issue is to post a user-defined message to the main window to signal that the user interface needs to be updated. The message handler would then process the user-defined message and update the user interface as needed.

The callback function specified by the *lpEventProc* parameter must be declared using the `__stdcall` calling convention. This ensures the arguments passed to the event handler are pushed on to the stack in the correct order. Failure to use the correct calling convention will corrupt the stack and cause the application to terminate abnormally.

The *dwParam* parameter is commonly used to identify the class instance which is associated with the event that has occurred. Applications will cast the *this* pointer to a `DWORD_PTR` value when calling this function, and then the event handler will cast it back to a pointer to the class instance. This gives the handler access to the class member variables and methods.

The **Wait** method can be used to wait for the queue manager to complete processing the transfer queue.

Example

```
// Create a new queue
CFtpQueue *pQueue = new CFtpQueue();

// Add a file to the queue
pQueue->AddFile(lpszLocalFile, lpszRemoteFile);

// Start the queued file transfers and wait for it to complete
if (pQueue->Start(FTP_QUEUE_ALL))
{
    pQueue->Wait(INFINITE);
    pQueue->Stop();
}

// Remove all files from the queue
delete pQueue;
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

See Also

[CFtpQueue](#), [~CFtpQueue](#), [Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Stop](#), [Suspend](#), [Wait](#)

CFtpQueue::Stop Method

BOOL Stop();

The **Stop** method stops transferring queued files.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

When the **Stop** method is called and there is a file transfer in progress, it will not immediately stop the upload or download of the file. Instead, the queue manager is signaled to stop processing additional files in the queue after the transfer has completed. To wait for the current transfer to complete, call the **Wait** method.

It is permitted to call the **Stop** method from within a queue event handler. In this case, the current file transfer will complete and the queue manager will terminate.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Start](#), [Suspend](#), [Wait](#)

CFtpQueue::Suspend Method

BOOL Suspend();

The **Suspend** method pauses all file transfers for the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

If there is a file transfer in progress when this method is called, the transfer will complete normally. The queue manager will enter a suspended state after the transfer has completed and before it begins processing the next file in the queue.

It is permitted to call the **Suspend** method from within a queue event handler. In this case, the current file transfer will complete and the queue manager will stop processing additional files in the queue until it is resumed or stopped.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Start](#), [Stop](#), [Wait](#)

CFtpQueue::Wait Method

```
BOOL WINAPI FtpWaitForQueue(  
    DWORD dwMilliseconds,  
    LPDWORD lpdwElapsed,  
    LPDWORD lpdwError  
);  
  
BOOL WINAPI FtpWaitForQueue(  
    DWORD dwMilliseconds  
);
```

The **Wait** method waits for the specified queue to complete the file transfers.

Parameters

dwMilliseconds

An unsigned integer value which specifies the number of milliseconds to wait for the queue to complete processing. If this value is zero, the method will return immediately. If this value is INFINITE (0xFFFFFFFF), the method will block indefinitely until all files in the queue have been processed.

lpdwElapsed

A pointer to an unsigned integer which will contain the number of milliseconds the queue manager has been active when the method returns. If this information is not needed, this parameter can be omitted or it can be NULL. If this parameter is not NULL, it will always be initialized to a value of zero.

lpdwError

A pointer to an unsigned integer which will contain the last error code set if a file transfer has failed or was canceled. If this information is not needed, this parameter can be omitted or NULL. If this parameter is not NULL, it will always be initialized to a value of zero.

Return Value

If the method succeeds, the return value is non-zero, which means the queue manager has completed transferring all queued files. If the method fails, or the timeout period elapses, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method will cause the current thread to block until either the queue manager has completed processing all files in the queue, or until the specified number of milliseconds have elapsed. It is important to note that Windows messages will not be processed during this time. If you call this method within the main UI thread, it can potentially cause the application to become non-responsive. To determine the current state of the queue without blocking the current thread, call the **GetStatus** method.

If the *dwMilliseconds* parameter is non-zero and file transfers have not completed within the specified amount of time, the method will return zero and the last error code will be set to **ST_ERROR_OPERATION_TIMEOUT**.

If an event callback function has been specified when starting the queue, you should never call this method within the event handler. Attempting to do so can potentially create a situation which will cause the application to become non-responsive. The method will return zero if it determines it's being called within the context of the queue manager thread and will set the last error code to **ST_ERROR_THREAD_DEADLOCK**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

File Transfer Queue Data Structures

- [FTPQUEUEDFILE](#)
- [FTPQUEUESTATUS](#)
- [FTPTRANSFERSTATUS](#)
- [FTPTRANSFERSTATUSEX](#)
- [SYSTEMTIME](#)

FTPQUEUEDFILE

This structure is used by the **GetFile**, **GetFirstFile** and **GetNextFile** methods to return information about a file in the transfer queue.

```
typedef struct _FTPQUEUEDFILE
{
    DWORD          dwFileId;
    DWORD          dwQueueMode;
    DWORD          dwQueueFlags;
    DWORD          dwTimeElapsed;
    DWORD          dwLastError;
    ULARGE_INTEGER uiBytesCopied;
    TCHAR          szLocalFile[FTP_MAXFILENAMELEN];
    TCHAR          szRemoteFile[FTP_MAXURLPATHLEN];
} FTPQUEUEDFILE, *LPFTPQUEUEDFILE;
```

Members

dwFileId

An unsigned integer which specifies a unique identifier for the queued file. The application should not make any assumptions about the value of the file identifiers. They should be considered opaque values which are only guaranteed to uniquely identify a file in the transfer queue. In particular, there is no guarantee that the file identifiers will be sequential and they should not be used as index values into an array.

dwQueueMode

An unsigned integer value which specifies how the file was queued for transfer. It may be one of the following values:

Constant	Description
FTP_QUEUE_DOWNLOAD	The file was queued for download.
FTP_QUEUE_UPLOAD	The file was queued for upload.

dwQueueFlags

An unsigned integer which specifies one or more bit flags which provides information about the status of the file transfer. It may be one or more of the following values:

Constant	Description
FTP_QUEUE_FLAG_NONE	The file is pending transfer in queue.
FTP_QUEUE_FLAG_COMPLETED	The file has been transferred successfully. If this flag is set, no errors were encountered during the upload or download.
FTP_QUEUE_FLAG_FAILED	The file transfer failed. If this flag is set, the <i>dwError</i> member of this structure will contain the error code associated with the failed transfer.
FTP_QUEUE_FLAG_CANCELED	The file transfer was canceled. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

dwTimeElapsed

An unsigned integer which specifies the number of milliseconds required to complete the transfer. This value will be zero unless the file has been transferred successfully.

dwLastError

An unsigned integer which specifies the last error code for a failed transfer. If the file was transferred successfully, this value will be zero.

uiBytesCopied

A value which specifies the number of bytes which were copied during the file transfer. The `ULARGE_INTEGER` type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

szLocalFile

A null terminated string which specifies the full path to the local file being transferred.

szRemoteUrl

A null terminated string which specifies the complete URL to the remote file being transferred.

Remarks

It is possible that the ***szLocalFile*** and ***szRemoteFile*** structure members will be different than the values passed to the **AddFile** method. Those values are normalized, with any relative paths converted to absolute paths. Internationalized domain names will be encoded and the URL paths will be collapsed, removing any extraneous path information. For example, if the remote file name is specified as **ftp://ftp.server.tld/folder1/./folder2/filename.txt** it would be normalized as **ftp://ftp.server.tld/folder2/filename.txt**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftpv11.lib`

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddFile](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#)

FTPQUEUESTATUS

This structure is used by the **GetStatus** method to return information about the current status of the file transfer queue.

```
typedef struct _FTPQUEUESTATUS
{
    DWORD dwStatus;
    DWORD dwThreadId;
    DWORD dwQueuedFiles;
    DWORD dwPendingFiles;
    DWORD dwCopiedFiles;
    DWORD dwFailedFiles;
    DWORD dwTimeElapsed;
    DWORD dwCurrentFile;
    DWORD dwLastError;
    ULARGE_INTEGER uiBytesCopied;
    ULARGE_INTEGER uiBytesTotal;
} FTPQUEUESTATUS, *LPFTPQUEUESTATUS;
```

Members

dwStatus

An unsigned integer which specifies the current status of the queue. It can be one of the following values:

Value	Description
FTP_QUEUE_STATUS_IDLE	The file transfer queue is idle and no files are being uploaded or downloaded. This state is returned before the Start method has been called or after the Stop method has been called. The queue will also automatically enter an idle state after the last file transfer has completed and the queue manager thread exits.
FTP_QUEUE_STATUS_ACTIVE	Files in the queue are being uploaded or downloaded. The <i>dwCurrentFile</i> member of this structure identifies the file which is currently being transferred.
FTP_QUEUE_STATUS_PAUSED	File transfers are currently paused. The queue enters this state after the Suspend method is called and resumes file transfers after the Resume method is called.

dwThreadId

An unsigned integer which specifies the thread ID for the queue manager which is performing the file transfers. All file transfers are performed asynchronously in a background worker thread. If this structure member is zero, the queue is idle and not performing file transfers. The application should not use the thread ID to obtain a handle to suspend or terminate the thread. This can potentially result in unexpected behavior or instability within the application.

dwQueuedFiles

An unsigned integer which specifies the total number of queued files. This value includes pending and completed file transfers.

dwPendingFiles

An unsigned integer which specifies the number of files which are queued to be transferred.

dwCopiedFiles

An unsigned integer which specifies the number of files which have been successfully transferred. This value reflects the total number of files which have the FTP_QUEUE_FLAG_COMPLETED status.

dwFailedFiles

An unsigned integer which specifies the number of files which have failed to transfer or the file transfer has been canceled. This value reflects the total number of files which have the FTP_QUEUE_FLAG_FAILED status.

dwTimeElapsed

An unsigned integer which specifies the total amount of time, in milliseconds, the queue manager has been active performing a file transfer. If the queue is idle, this value will reflect the total run time for the previously active queue. A value of zero indicates the queue was never active or the queue state has been reset with a call to the **Reset** method.

dwCurrentFile

An unsigned integer which specifies the unique identifier for the current file being transferred. If no file transfer is in progress, this member will have a value of zero. If the value is non-zero, it can be passed to the **GetFile** method to obtain information about the queued file.

dwLastError

An unsigned integer which specifies the last error code for a failed file transfer. If there have been no errors, this value will be zero.

uiBytesCopied

A value which specifies the number of bytes which were copied during the current or last transfer. The ULARGE_INTEGER type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

uiBytesTotal

A value which specifies the total number of bytes which were copied during the current queue run. The ULARGE_INTEGER type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[GetFile](#), [GetStatus](#), [Cancel](#), [Reset](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#)

FTPTRANSFERSTATUS

This structure is used by the **GetTransferStatus** method to return information about a file transfer in progress.

```
typedef struct _FTPTRANSFERSTATUS
{
    DWORD    dwBytesTotal;
    DWORD    dwBytesCopied;
    DWORD    dwBytesPerSecond;
    DWORD    dwTimeElapsed;
    DWORD    dwTimeEstimated;
    TCHAR    szLocalFile[FTP_MAXFILENAMELEN];
    TCHAR    szRemoteFile[FTP_MAXFILENAMELEN];
} FTPTRANSFERSTATUS, *LPFTPTRANSFERSTATUS;
```

Members

dwBytesTotal

The total number of bytes that will be transferred. If the file is being copied from the server to the local host, this is the size of the remote file. If the file is being copied from the local host to the server, it is the size of the local file. If the file size cannot be determined, this value will be zero.

dwBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the file transfer is completed. This is based on the average number of bytes transferred per second.

szLocalFile

A pointer to a string which specifies the local file that is being copied to or from the server.

szRemoteFile

A pointer to a string which specifies the remote file that is being copied to or from the local system.

Remarks

If the option `FTP_OPTION_HIRES_TIMER` has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small files over a fast network connection.

If you are uploading or downloading large files which exceed 4GB, you should use the **FTPTRANSFERSTATUSEX** structure which uses 64-bit integers for the file size.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

See Also

[GetTransferStatus](#), [FTPTRANSFERSTATUSEX](#)

FTPTRANSFERSTATUSEX

This structure is used by the **GetTransferStatus** method to return information about a file transfer in progress. This structure is designed for use with extended functions that support files larger than 4GB.

```
typedef struct _FTPTRANSFERSTATUSEX
{
    ULARGE_INTEGER dwBytesTotal;
    ULARGE_INTEGER dwBytesCopied;
    DWORD          dwBytesPerSecond;
    DWORD          dwTimeElapsed;
    DWORD          dwTimeEstimated;
    DWORD          dwReserved;
    TCHAR          szLocalFile[FTP_MAXFILENAMELEN];
    TCHAR          szRemoteFile[FTP_MAXFILENAMELEN];
} FTPTRANSFERSTATUSEX, *LPFTPTRANSFERSTATUSEX;
```

Members

uiBytesTotal

The total number of bytes that will be transferred. If the file is being copied from the server to the local host, this is the size of the remote file. If the file is being copied from the local host to the server, it is the size of the local file. If the file size cannot be determined, this value will be zero.

uiBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the file transfer is completed. This is based on the average number of bytes transferred per second.

dwReserved

This structure member is reserved for future use.

szLocalFile

A pointer to a string which specifies the local file that is being copied to or from the server.

szRemoteFile

A pointer to a string which specifies the remote file that is being copied to or from the local system.

Remarks

If the option `FTP_OPTION_HIRES_TIMER` has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small files over a fast network connection.

SYSTEMTIME

The **SYSTEMTIME** structure represents a date and time using individual members for the month, day, year, weekday, hour, minute, second, and millisecond.

```
typedef struct _SYSTEMTIME
{
    WORD wYear;
    WORD wMonth;
    WORD wDayOfWeek;
    WORD wDay;
    WORD wHour;
    WORD wMinute;
    WORD wSecond;
    WORD wMilliseconds;
} SYSTEMTIME, *LPSYSTEMTIME;
```

Members

wYear

Specifies the current year. The year value must be greater than 1601.

wMonth

Specifies the current month. January is 1, February is 2 and so on.

wDayOfWeek

Specifies the current day of the week. Sunday is 0, Monday is 1 and so on.

wDay

Specifies the current day of the month

wHour

Specifies the current hour.

wMinute

Specifies the current minute

wSecond

Specifies the current second.

wMilliseconds

Specifies the current millisecond.

File Transfer Protocol Server Class

Implements a server that enables the application to send and receive files using the File Transfer Protocol.

Reference

- [Event Handlers](#)
- [Data Structures](#)
- [Error Codes](#)

Library Information

File Name	CSFTSV11.DLL
Version	11.0.2218.1855
LibID	263021C1-CB49-4122-9D4B-244AA9EFF668
Import Library	CSFTSV11.LIB
Dependencies	None
Standards	RFC 959, RFC 1579, RFC 2228

Overview

This library provides an interface for implementing an embedded, lightweight server that can be used to exchange files with a client using the standard File Transfer Protocol. The server can accept connections from any third-party application or a program developed using the SocketTools FTP client API.

The application specifies an initial server configuration and then responds to events that are raised by the API when the client sends a request to the server. An application may implement only minimal handlers for most events, in which case the default actions are performed for most standard FTP commands. However, an application may also use the event mechanism to filter specific commands or to extend the protocol by providing custom implementations of existing commands or add entirely new commands.

The server supports active and passive mode file transfers, has compatibility options for NAT router and firewall support, and provides support for secure file transfers using explicit TLS. Secure connections require a valid security certificate to be installed on the system.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical

updates available for your version of the operating system.

This class provides an implementation of a multithreaded server which should only be used with languages that support the creation of multithreaded applications. It is important that you do not attempt to link against static libraries which were not built with support for threading.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

CFtpServer Public Data Members

Member Variables	Description
m_dwOptions	Options specified when creating an instance of the server
m_nAuthFail	The maximum number of user authentication failures permitted per client session
m_nAuthTime	The maximum number of seconds a client has to successfully authenticate the session
m_nExecTime	The maximum number of seconds that the server will permit an external command to execute
m_nIdleTime	The maximum number of seconds a client can be idle before the server terminates the session
m_nLogFormat	The format used by the server to log client activity
m_nLogLevel	The level of detail included in the server log file
m_nMaxClients	The maximum number of active client sessions accepted by the server
m_nMaxClientsPerAddress	The maximum number of clients per IP address accepted by the server
m_nMaxGuests	The maximum number of anonymous client sessions accepted by the server
m_nMaxPort	The maximum port number used by the server for passive data connections
m_nMinPort	The minimum port number used by the server for passive data connections

CFtpServer::m_dwOptions

DWORD m_dwOptions;

The default options used when starting an instance of the server.

Remarks

The **m_dwOptions** data member is a public variable that specifies the default options that should be used when starting an instance of the server. This variable can be modified directly or by calling the **SetOptions** method. For a list of available server options, see [Server Option Constants](#). Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#), [GetOptions](#), [SetOptions](#)

CFtpServer::m_nAuthFail

UINT m_nAuthFail;

The maximum number of user authentication failures permitted per client session.

Remarks

The **m_nAuthFail** data member is a public variable that specifies the maximum number of user authentication attempts that are permitted until the server terminates the client connection. A value of zero specifies that the default configuration limit of 3 authentication attempts per login should be allowed. The maximum number of authentication attempts is 10. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#)

CFtpServer::m_nAuthTime

UINT m_nAuthTime;

The maximum number of seconds a client has to successfully authenticate the session.

Remarks

The **m_nAuthTime** data member is a public variable that specifies the maximum number of seconds that a client session must authenticate itself. A value of zero specifies the default value of 60 seconds. If the value is non-zero, the minimum value is 20 seconds and the maximum value is 300 seconds (5 minutes). This value is used to ensure that a client has successfully authenticated itself within a limited period of time.

This time limit prevents a potential denial-of-service attack against the server where clients establish connections and hold them open without authentication. In conjunction with the **m_nAuthFail** data member, this also limits the ability of a client to attempt to probe the server for valid username and password combinations. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#)

CFtpServer::m_nExecTime

UINT m_nExecTime;

The maximum number of seconds that the server will permit an external command to execute.

Remarks

The **m_nExecTime** data member is a public variable that specifies the maximum number of seconds that an external program is permitted to run on the server. External programs are registered using the **RegisterProgram** method, and are executed by the client sending the SITE EXEC command to the server. If this value is zero, the default timeout period of 5 seconds will be used. The minimum execution time is 1 second and the maximum time limit is 30 seconds. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#), [RegisterProgram](#)

CFtpServer::m_nIdleTime

UINT m_nIdleTime;

The maximum number of seconds a client can be idle before the server terminates the session.

Remarks

The **m_nIdleTime** data member is a public variable that specifies the maximum number of seconds that a client session may be idle before the server closes the control connection to the client. A value of zero specifies the default value of 900 seconds (15 minutes). If the value is non-zero, the minimum value is 60 seconds and the maximum value is 7200 seconds (2 hours). This value is used to initialize the default idle timeout period for each client session. A client may request that the server change the idle timeout period for its session by sending the SITE IDLE command. The server determines if a client is idle based on the time the last command was issued and whether or not a file transfer is in progress. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#), [RegisterProgram](#)

CFtpServer::m_nLogFormat

UINT m_nLogFormat;

The format used when updating the server log file.

Remarks

The **m_nLogFormat** data member is a public variable that specifies the format of the log file that is created or updated by the server. It may be one of the following values:

Value	Description
FTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
FTP_LOGFILE_COMMON	This value specifies that the log file should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about file transfers.
FTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session.

By default, logging is not enabled for the server. Changing the value of this data member does not have an effect on an active instance of the server. To change the format, level of detail or default log file name, use the **SetLogFile** method.

See Also

[CFtpServer](#), [GetLogFile](#), [SetLogFile](#)

CFtpServer::m_nLogLevel

UINT m_nLogLevel;

The level of detail included in the server log file.

Remarks

The **m_nLogLevel** data member is a public variable that specifies the level of detail that should be generated in the log file. The minimum value is 1 and the maximum value is 10. If the **m_nLogFormat** data member specifies a valid log file format and this value is zero, a default level of detail will be selected based on the format.

The common log file format generally contains less information by default, only logging the data transfers between the client and server. The W3C extended log file format defaults to a higher level of detail that includes additional information about the client session. The higher the level of detail, the larger the log file will be.

By default, logging is not enabled for the server. Changing the value of this data member does not have an effect on an active instance of the server. To change the format, level of detail or default log file name, use the **SetLogFile** method.

See Also

[CFtpServer](#), [GetLogFile](#), [SetLogFile](#)

CFtpServer::m_nMaxClients

`UINT m_nMaxClients;`

The maximum number of clients that are permitted to connect to the server.

Remarks

The **m_nMaxClients** data member is a public variable that specifies the maximum number of clients that are permitted to establish a connection with the server. After this limit is reached, the server will reject additional connections until the number of active clients drops below this threshold. A value of zero specifies that there is no fixed limit on the active number of client connections. Changing the value of this data member does not have an effect on an active instance of the server. To change the maximum number of clients on an active server, use the **Throttle** method.

The actual number of client connections that can be accepted depends on the amount of memory available to the server process. Sockets are allocated from the non-paged memory pool, so the actual number of sockets that can be created system-wide depends on the amount of physical memory that is installed. If the server will be accessible over the Internet, it is recommended that you limit the maximum number of client connections to a reasonable value.

See Also

[CFtpServer](#), [Throttle](#)

CFtpServer::m_nMaxClientsPerAddress

UINT m_nMaxClientsPerAddress;

The maximum number of clients that are permitted to connect to the server from a single IP address.

Remarks

The **m_nMaxClientsPerAddress** data member is a public variable that specifies the maximum number of clients that are permitted to establish a connection with the server from a single IP address. After this limit is reached, the server will reject additional connections until the number of active clients drops below this threshold. A value of zero specifies that there is no limit on the active number of client connections per IP address. Changing the value of this data member does not have an effect on an active instance of the server. To change the maximum number of clients on an active server, use the **Throttle** method.

See Also

[CFtpServer](#), [Throttle](#)

CFtpServer::m_nMaxGuests

UINT m_nMaxGuests;

The maximum number of anonymous users that are permitted to connect to the server.

Remarks

The **m_nMaxGuests** data member is a public variable that specifies the maximum number of anonymous users that are permitted to establish a connection with the server. After this limit is reached, the server will send an error response indicating that the server is unavailable, and then immediately terminate the session. Unlike the limit on the total number of client connections, this limit is only checked after the client has requested authentication and has logged in as an anonymous user. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#)

CFtpServer::m_nMaxPort

UINT m_nMaxPort;

The maximum port number used by the server for passive data connections.

Remarks

The **m_nMaxPort** data member is a public variable that specifies the maximum range of port numbers that will be used with passive data connections. A value of zero specifies the default value of 65535 should be used. The minimum value of this member is 5000 and the maximum value is 65535. If the value is non-zero, it must be greater than the value of the **m_nMinPort** data member. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CFtpServer](#)

CFtpServer::m_nMinPort

UINT m_nMinPort;

The minimum port number used by the server for passive data connections.

Remarks

The **m_nMinPort** data member is a public variable that specifies the minimum range of port numbers that will be used with passive data connections. A value of zero specifies that the default value of 30000 should be used. The minimum value of this member is 5000 and the maximum value is 65535. If the value is non-zero, it must be less than the value of the **m_nMaxPort** data member. Changing the value of this data member does not have an effect on an active instance of the server.

CFtpServer Methods

Class	Description
CFtpServer	Constructor which initializes the current instance of the class
~CFtpServer	Destructor which releases resources allocated by the class
Method	Description
AddVirtualUser	Add a new virtual user for the specified server
AsyncNotify	Enable or disable asynchronous notification of changes in server status
AttachHandle	Attach the specified server handle to this instance of the class
AuthenticateClient	Authenticate the client and assign access rights for the session
ChangeClientDirectory	Change the current working directory for the client session
DeleteVirtualUser	Delete a virtual user from the specified server
DetachHandle	Detach the server handle from the current instance of this class
DisableCommand	Disable a specific server command
DisableTrace	Disable the logging of network function calls
DisconnectClient	Disconnect the specific client session, closing the control channel and aborting any file transfer
EnableClientAccess	Enable or disable access rights for the specified client session
EnableCommand	Enable a specific server command
EnableTrace	Enable logging of network function calls to a file
EnumClients	Returns a list of active client connections established with the server
GetActiveClient	Return the client ID for the active client session associated with the current thread
GetAddress	Return the IP address for the server
GetClientAccess	Return the access rights that have been granted to the client session
GetClientAddress	Return the IP address of the specified client session
GetClientCredentials	Return the credentials for the specified client session
GetClientDirectory	Return the current working directory for a client session
GetClientFileType	Return the current file type used for transfers by the specified client
GetClientHomeDirectory	Return the home directory for an authenticated client session
GetClientIdentity	Return the identity of the specified client session
GetClientIdleTime	Return the idle timeout period for the specified client
GetClientLocalPath	Return the full local path for the specified virtual path
GetClientServer	Return the handle to the server that created the specified client session
GetClientThreadId	Returns the thread ID associated with the specified client session

GetClientUserName	Return the user name associated with the specified client session
GetClientVirtualPath	Return the virtual path for a local file on the server
GetCommandFile	Return the full path to the local file name or directory specified by the client
GetCommandLine	Return the complete command line issued by the client
GetCommandName	Return the name of the last command issued by the client
GetCommandParam	Return the value of the specified parameter for the command issued by the client
GetCommandParamCount	Return the number of parameters to the current command issued by the client
GetCommandResult	Return the result code and a description of the last command processed by the server
GetCommandUsage	Return the number of times a specific command has been issued by all clients
GetDirectory	Return the full path to the root directory assigned to the specified server
GetHandle	Return the server handle associated with the class instance
GetIdentity	Return the identity and version information for the specified server
GetLastError	Return information about the last server error that occurred
GetLogFile	Return the current log file format and full path for the file
GetMemoryUsage	Return the amount of memory allocated for the server and all client sessions
GetName	Return the host name assigned to the server or specified client session
GetOptions	Return the options specified for this instance of the server
GetPriority	Return the current priority assigned to the specified server
GetProgramExitCode	Return the exit code of the last program executed by the client
GetProgramName	Return the name of the last program executed by the client
GetProgramOutput	Return a copy of the standard output from the last program executed by the client
GetProgramText	Return a copy of the standard output from the last program in a string buffer
GetRenamedFile	Return the original name of a file being renamed by the client
GetStackSize	Return the initial size of the stack allocated for threads created by the server
GetTransferInfo	Return information about the current file transfer for the client session
GetUuid	Return the UUID assigned to the specified server
IsActive	Determine if the server has been started
IsClientAnonymous	Determine if the specified client has authenticated as an anonymous user
IsClientAuthenticated	Determine if the specified client session has been authenticated
IsCommandEnabled	Determine if the specified command is currently enabled or disabled
IsInitialized	Determine if the class has been successfully initialized
IsListening	Determine if the server is listening for client connections
PreProcessEvent	Filter server events before being processed by the default event handler

RegisterProgram	Register a program for use with the SITE EXEC command
RenameServerLogFile	Rename or delete the current log file being updated by the server
Restart	Restart the server, terminating all active client sessions
Resume	Resume accepting client connections on the specified server
SendResponse	Send a result code and optional message to the client in response to a command
SetAddress	Change the IP address that the server will use with passive data connections
SetCertificate	Set the name of the certificate to be used with secure connections.
SetClientAccess	Change the access rights associated with the specified client session
SetClientFileType	Change the current file type used for transfers by the specified client
SetClientIdentity	Change the identity string associated with the specified client session
SetClientIdleTime	Change the idle timeout period for the specified client session
SetCommandFile	Change the name of the local file or directory that is the target of the current command
SetDirectory	Specify the local directory that will be used as the server root directory
SetLastError	Set the last error code for the specified server session
SetLogFile	Change the current log format, level of detail and file name
SetIdentity	Change the identity and version information for the specified server
SetName	Change the hostname assigned to the server or specified client session
SetOptions	Change the options specified for this instance of the server
SetPriority	Change the priority assigned to the specified server
SetStackSize	Change the initial size of the stack allocated for threads created by the server
SetUuid	Assign a UUID to be associated with this instance of the server
Start	Start the server and begin accepting client connections
Stop	Stop the server and terminate all active client connections
Suspend	Suspend accepting client connections on the specified server
Throttle	Limit the number of active client connections, connections per address and connection rate

CFtpServer::~CFtpServer

`~CFtpServer();`

The **CFtpServer** destructor releases resources allocated by the current instance of the **CFtpServer** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CFtpServer** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CFtpServer](#)

CFtpServer::AddVirtualUser Method

```
BOOL AddVirtualUser(  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    DWORD dwUserAccess,  
    LPCTSTR lpszDirectory  
);
```

Add a new virtual user for the specified server.

Parameters

lpszUserName

A pointer to a string which specifies the user name. The maximum length of a username is 63 characters and it is recommended that names be limited to alphanumeric characters. Whitespace, control characters and certain symbols such as path delimiters and wildcard characters are not permitted. If an invalid character is included in the name, the method will fail with an error indicating the username is invalid. This parameter cannot be NULL and the name must be at least three characters in length. Usernames are not case sensitive.

lpszPassword

A pointer to a string which specifies the user password. The maximum length of a password is 63 characters and is limited to printable characters. Whitespace and control characters are not permitted. If an invalid character is included in the password, the method will fail with an error indicating the password is invalid. This parameter cannot be NULL and must be at least one character in length. Passwords are case sensitive.

dwUserAccess

An integer value which specifies the access clients will be given when authenticated as this user. For a list of user access permissions, see [User Access Constants](#).

lpszDirectory

A pointer to a string which specifies the directory that will be the virtual user's home directory. If the server was started in multi-user mode, this directory will be relative to the user directory created by the server, otherwise it will be relative to the server root directory. If the directory does not exist, it will be created the first time that the virtual user successfully logs in to the server. If this parameter is NULL or an empty string, a default home directory will be created for the virtual user.

Return Value

If the method succeeds, the return value is non-zero. If the username or password contain invalid characters, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **AddVirtualUser** method adds a virtual user that is associated with the specified virtual host. When a client connects with the server and provides authentication credentials, the server will check if the username has been created using this method. If a match is found, the client access rights will be updated.

If you wish to modify the information for a user, it is not necessary to delete the username first. If this method is called with a username that already exists, that record is replaced with the values passed to this method. You cannot use this method to create a virtual user named "anonymous".

The virtual users created by this method exist only as long as the server is active. If you wish to maintain a persistent database of users and passwords, you are responsible for its implementation based on the requirements of your specific application. For example, a simple implementation would be to store the user information in a local XML or INI file and then read that configuration file after the server has started, calling this method for each user that is listed.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DeleteVirtualUser](#)

CFtpServer::AsyncNotify Method

```
BOOL AsyncNotify(  
    HWND hWnd,  
    UINT uMsg  
);
```

Enable or disable asynchronous notification of changes in server status.

Parameters

- hWnd**
A handle to the window whose window procedure will receive the notification message.
- uMsg**
The user-defined message that will be sent to the notification window.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **AsyncNotify** method is used by an application to enable or disable asynchronous notifications. The message window is typically the main UI window and these notifications are used signal to the application that it should update the user interface. If the **hWnd** parameter is not NULL, it must specify a valid window handle and the user-defined message must have a value of **WM_USER** or higher. The application cannot specify a notification message that is reserved by the operating system. The pseudo-handle **HWND_BROADCAST** cannot be specified as the notification window. If the **hWnd** parameter is NULL, notifications for the specified server will be disabled.

When asynchronous notifications are enabled for a server, the server will post the user-defined message to the window whenever there is a change in status or after a client has connected or disconnected from the server. The **wParam** message parameter will contain the notification message and the **lParam** message parameter will contain the handle to the server or the client ID. The following notification messages are defined:

Value	Description
FTP_NOTIFY_STARTUP	This notification is sent when the server has started and is preparing to accept client connections. This notification is only sent once, and only if asynchronous notifications are enabled immediately after the Start method is called. This message will not be sent once the server has begun accepting client connections or when notification messages are disabled and then subsequently re-enabled at a later time. The lParam message parameter will specify the handle to the server.
FTP_NOTIFY_LISTEN	This notification is sent when the server is listening for client connections. This notification message may be sent to the application multiple times over the lifetime of the server. If the server was suspended, this notification will be sent after the application calls the Resume method to resume accepting client connections. The lParam message parameter will

	specify the handle to the server.
FTP_NOTIFY_SUSPEND	This notification is sent when the server suspends accepting new connections because the application has called the Suspend method. This notification message may be sent to the application multiple times over the lifetime of the server. The <i>lParam</i> message parameter will specify the handle to the server.
FTP_NOTIFY_RESTART	This notification is sent when the server is restarted using the Restart method. Note that the server socket handle provided by the <i>lParam</i> message parameter will specify the new socket handle of the restarted server instance, not the original socket handle. The <i>lParam</i> message parameter will specify the handle to the server.
FTP_NOTIFY_CONNECT	This notification is sent when the server accepts a client connection and the thread that manages the client session has begun processing network events for that client. This message notification will not be sent if the client connection is rejected by the server. The <i>lParam</i> message parameter will specify the unique ID of the client that connected to the server.
FTP_NOTIFY_DISCONNECT	This notification is sent when the client disconnects from the server and the client socket has been closed. This notification message may not occur for each client session that is forced to terminate as the result of the server being stopped using the Stop method. The <i>lParam</i> message parameter will specify the unique ID of the client that disconnected from the server.
FTP_NOTIFY_SHUTDOWN	This notification is sent when the server thread is in the process of terminating. At the time the application processes this notification message, the server handle in <i>lParam</i> will reference the defunct server and cannot be used with other server methods. The <i>lParam</i> message parameter will specify the handle to the server.

If asynchronous notifications are enabled, you should never use those notifications as a replacement for an event handler. When an event occurs, the callback function that handles the event is invoked in the context of the thread that manages the client session. The application should exchange data with the client within that event handler and not in response to a notification message. These notification messages should only be used to update the application UI in response to changes in the status of the server.

The FTP_NOTIFY_CONNECT and FTP_NOTIFY_DISCONNECT notifications are different from the other server notifications because the *lParam* message parameter does not specify the server handle, but rather the unique client ID associated with the session that connected to or disconnected from the server. Use the **GetClientServer** method to obtain a handle to the server that created the client session. Note that at the time the application processes the FTP_NOTIFY_DISCONNECT notification message, the client session will have already terminated.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpServer::AttachHandle Method

```
VOID AttachHandle(  
    HSERVER hServer  
);
```

The **AttachHandle** method attaches the specified server handle to the current instance of the class.

Parameters

hServer

The handle to the server that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a server handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that server.

If a server handle already has been created for the class, that handle will be released when the new handle is attached to the class object. This will cause the server to stop and all client sessions will be terminated immediately. If you want to prevent the previous server from being stopped, you must call the **DetachHandle** method prior to attaching a new handle to the class instance.

Note that the *hServer* parameter is presumed to be a valid server handle and no checks are performed to ensure that the handle references an active server. Specifying an invalid server handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

[DetachHandle](#), [GetHandle](#)

CFtpServer::AuthenticateClient Method

```
BOOL AuthenticateClient(  
    UINT nClientId,  
    DWORD dwUserAccess,  
    BOOL bCreateHome,  
    LPCTSTR lpszDirectory  
);
```

Authenticate the client and assign access rights for the session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more user access rights. For a list of user access rights that can be granted to the client, see [User Access Constants](#).

bCreateHome

An integer value that specifies if the server should create the home directory for the authenticated client if it does not already exist. If this value is non-zero, the home directory will be created. If value is zero, the home directory will not be created and if it does not exist, this function will fail.

lpszDirectory

A pointer to a string that specifies the home directory for the user. If an absolute path is specified, it will be relative to the server root directory. If a relative path is specified, it will be a subdirectory of the home directory for the server instance. If this parameter is NULL or an empty string, a home directory will be assigned based on the server home directory and the user name.

Return Value

If the the client session could be authenticated, the return value is non-zero. If the client ID does not specify a valid client session, or the client has already been authenticated, this method will return zero.

Remarks

The **AuthenticateClient** method is used to authenticate a specific client session, typically in response to an **OnAuthenticate** event that indicates a client has requested authentication. This method is also used internally to automatically grant the appropriate access rights to local user and anonymous client sessions.

It is recommended that most applications specify FTP_ACCESS_DEFAULT as the *dwUserAccess* value for a client session, since this allows the server automatically grant the appropriate access based on the server configuration options for normal and anonymous users. If the server is going to be publicly accessible or third-party FTP clients will be used to access the server, you should always grant the FTP_ACCESS_LIST permission to clients. Many client applications will not function correctly if they are unable to obtain a list of files in the user's home directory.

If FTP_ACCESS_RESTRICTED is specified and the server was started in multi-user mode, the client session will be effectively locked to its home directory and cannot navigate to the server root directory. By default, restricted client sessions are also limited to only downloading files and requesting directory listings. If a client session is not restricted, the client can access files outside of its home directory. Regardless of this option, a client cannot access files outside of the server root directory.

If FTP_ACCESS_RESTRICTED or FTP_ACCESS_ANONYMOUS is specified, the client session will be

authenticated in a restricted mode and the access rights for the session will persist until the client disconnects from the server. Unlike regular users, the access rights for a restricted client cannot be changed by the server at a later point. This restriction is designed to prevent the inadvertent granting of rights to an untrusted client that could compromise the security of the server.

If the *lpzDirectory* parameter is NULL or an empty string and the server has been started in multi-user mode, each user is assigned their own home directory based on their username. If the server has not been started in multi-user mode, then the default home directory will be the server root directory and is shared by all users. The **GetClientHomeDirectory** method will return the full path to the home directory for an authenticated client.

If the FTP_ACCESS_EXECUTE permission is granted to the client session, it can execute external programs using the SITE EXEC command. Because the program is executed in the context of the server process, it is recommended that you limit access to this functionality and ensure that the programs being executed do not introduce any security risks to the operating system. This permission is never granted by default, and the SITE EXEC command will return an error if the client session is anonymous, regardless of whether this permission is granted or not.

This method should only be used for custom authentication schemes and is not necessary if you have used the **AddVirtualUser** method to create virtual users.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CFtpServer::CFtpServer Method

CFtpServer();

The **CFtpServer** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **FtpServerInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** method because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[~CFtpServer](#), [IsInitialized](#)

CFtpServer::ChangeClientDirectory Method

```
BOOL ChangeClientDirectory(  
    UINT nClientId,  
    LPCTSTR lpszDirectory  
);
```

Change the current working directory for the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszDirectory

A pointer to a string which specifies the new current working directory for the client session. If this parameter is NULL or an empty string, the current working directory will be changed to the client home directory. If this parameter is not NULL, it must specify a directory that exists and is accessible by the server process.

Return Value

If the current working directory was changed, the return value is non-zero. If the client ID does not specify a valid client session, or the directory is invalid, this method will return zero.

Remarks

The **ChangeClientDirectory** method will change the current working directory for the specified client session. This method is called internally when the client sends the CWD or CDUP commands, however it may be explicitly used by the application to change the client's working directory in response to a server event.

This method cannot be used to change the current working directory for a client to an arbitrary directory outside of the server root directory. If the *lpszDirectory* parameter specifies a relative path (i.e.: a path that does not begin with a drive letter or leading path delimiter) then the new working directory will be relative to the current working directory. If an absolute path is specified, the absolute path must include the complete path to either the server root directory or the user's home directory, based on the permissions granted to the client session. If a path outside of the server root directory is specified, this method will fail with an access denied error.

Use caution when calling this method to override the directory specified by the client when it sends the CWD or CDUP commands. If your application changes the current working directory to one not specified by the client, it may cause unpredictable behavior in the client application because the actual path of the current working directory will not match the directory that was requested.

If this method is used to change the current working directory in response to the CWD command, you should not call the **GetCommandParam** method and pass the command parameter as an argument to this method. You must use the **GetCommandFile** method to obtain the directory name provided by the client prior to calling this method.

The application should never call the **SetCurrentDirectory** function in the Windows API to change the current directory for the process to the working directory of a client session. Because the server is multithreaded and each client session is managed in its own thread, an application using this library should avoid using relative paths.

Requirements

CFtpServer::DeleteVirtualUser Method

```
BOOL DeleteVirtualUser(  
    UINT nHostId,  
    LPCTSTR lpszUserName  
);
```

Remove a virtual user from the specified host.

Parameters

nHostId

An integer value which identifies the virtual host. This parameter is reserved for future use and must always have a value of zero.

lpszUserName

A pointer to a string which specifies the user that will be removed. This parameter cannot be a NULL pointer or an empty string.

Return Value

If the method succeeds, the return value is non-zero. If the virtual host ID does not specify a valid host, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

This method removes a virtual user that was created by a previous call to the **AddVirtualUser** method. This method will not match partial usernames and wildcard characters cannot be used to delete multiple users. Usernames are not case sensitive. You cannot use this method to delete the "anonymous" user.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AddVirtualUser](#)

CFtpServer::DetachHandle Method

HSERVER DetachHandle();

The **DetachHandle** method detaches the server handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the server handle associated with the current instance of the class object. If there is no active server, the value `INVALID_SERVER` will be returned.

Remarks

This method is used to detach a server handle created by the class for use with the SocketTools API. Once the server handle is detached from the class, no other class member functions may be called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftsv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CFtpServer::DisableCommand Method

```
BOOL DisableCommand(  
    LPCTSTR lpszCommand  
);
```

Disable a specific server command.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command to be enabled or disabled. The command name is not case-sensitive, but the value must otherwise match the exact name. Partial matches are not recognized by this method. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the command is not recognized, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **DisableCommand** method is used to disable access to a specific command on the server. When a command is disabled, it will also disable any corresponding feature related to that command. For example, if the MDTM command is disabled and a client issues the FEAT command to request a list of supported features, the command will no longer be listed. This method is typically used to disable certain commands for compatibility with older client software. The **IsCommandEnabled** method can be used to determine if a command is enabled or not.

The command name provided to this method must match the commands defined in RFC 959 or related protocol standards. It is important to distinguish between commands recognized by an FTP server and the commands that client programs may use. For example, the standard Windows FTP command line program provides commands such as GET and PUT to download and upload files. However, those are not the actual commands sent to a server. Instead, the corresponding server commands issued by a client application would be RETR (retrieve) and STOR (store). Refer to [File Transfer Protocol Commands](#) for a complete list of server commands.

Some commands cannot be disabled because they are required to perform essential server functions. For example, the USER and PASS commands are required to perform client authentication and therefore cannot be disabled. If you attempt to disable a required command, this method will return zero and the last error code will be set to ST_ERROR_COMMAND_REQUIRED. Because this method affects all clients connected to the server, it should not be used to limit access to certain commands for specific clients. Instead, either assign the client the appropriate permissions using the **AuthenticateClient** method, or use an event handler to filter the commands.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[EnableTrace](#)

CFtpServer::DisconnectClient Method

```
BOOL DisconnectClient(  
    UINT nClientId  
);
```

Close the control connection for the specified client and release the resources allocated for the session

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **DisconnectClient** method will close the control channel, disconnecting the client from the server and terminating the client session thread. Resources that we allocated for the client, such as memory and open handles, will be released back to the operating system. If the client was in the process of transferring a file, the transfer will be aborted. This performs the same operation as if the client sent the QUIT command to the server.

This method sends an internal control message that notifies the server that this session should be terminated. When the session thread is signaled that it should terminate, it will abort any active file transfers and begin to release the resources allocated for that session. To ensure that the client session terminates gracefully, there may be a brief period of time where the session thread is still active after this method has returned.

After this method returns, the application should never use the same client ID with another method. Client IDs are unique to the session over the lifetime of the server, and are not reused.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

[Restart](#), [Stop](#)

CFtpServer::EnableClientAccess Method

```
BOOL EnableClientAccess(  
    UINT nClientId,  
    DWORD dwUserAccess,  
    BOOL bEnable  
);
```

Enable or disable access rights for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies an access right to enable or disable. For a list of user access rights that can be granted to the client, see [User Access Constants](#).

bEnable

An integer value which specifies if permission should be granted or revoked for the specified access right. If this value is non-zero, permission is granted to the client to perform the action specified by the *dwUserAccess* parameter. If this value is zero, that permission is revoked.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method can only be used with authenticated clients. If the client session has not been authenticated, the return value will be zero.

Remarks

The **EnableClientAccess** method is used to enable or disable access to specific functionality by the client. The method can only change a single access right and cannot be used to enable or disable multiple access rights in a single method call. To change multiple user access rights for the client, use the **SetClientAccess** method.

This method cannot be used to change the access rights for a restricted or anonymous user. Those rights are granted when the client session is authenticated and will persist until the client disconnects from the server. This restriction is designed to prevent the inadvertent granting of rights to an untrusted client that could compromise the security of the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[AuthenticateClient](#), [GetClientAccess](#), [SetClientAccess](#)

CFtpServer::EnableCommand Method

```
BOOL EnableCommand(  
    LPCTSTR lpszCommand  
);
```

Enable a specific server command.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command to be enabled or disabled. The command name is not case-sensitive, but the value must otherwise match the exact name. Partial matches are not recognized by this method. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the command is not recognized, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **EnableCommand** method is used to enable access to a specific command on the server. When a command is enabled, it will also enable any corresponding feature related to that command. For example, if the MDTM command is enabled and a client issues the FEAT command to request a list of supported features, the command will be included in the list. The **IsCommandEnabled** method can be used to determine if a command is enabled or not.

The command name provided to this method must match the commands defined in RFC 959 or related protocol standards. It is important to distinguish between commands recognized by an FTP server and the commands that client programs may use. For example, the standard Windows FTP command line program provides commands such as GET and PUT to download and upload files. However, those are not the actual commands sent to a server. Instead, the corresponding server commands issued by a client application would be RETR (retrieve) and STOR (store). Refer to [File Transfer Protocol Commands](#) for a complete list of server commands.

[AuthenticateClient](#), [DisableCommand](#), [IsCommandEnabled](#)

CFtpServer::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

Enable the logging of network function calls to a file.

Parameters

lpszTraceFile

A pointer to a string that specifies the name of the log file. If this parameter is NULL or points to an empty string, a log file is created in the temporary directory for the current user.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_DEFAULT	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail, or return values which indicate a warning, are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call [GetLastError](#).

Remarks

When trace logging is enabled, the log file is opened, appended to and closed for each socket function call. Using the same file name, you can do the same in your application to add additional information to the file if needed. This can provide an application-level context for the entries made by the library. Make sure that the file is closed after the data has been written. If a file name is not specified by the caller, a file named **cstrace.log** will be created in the temporary directory for the current user.

The TRACE_HEXDUMP option can produce very large files, since all data that is being sent and received by the application is logged. To reduce the size of the file, you can enable and disable logging around limited sections of code that you wish to analyze.

To redistribute an application that includes this debug logging functionality, the **cstrcv11.dll** library must be included as part of the installation package. This library provides the trace logging features, and if it is not available the **EnableTrace** method will fail. Note that this is a standard Windows DLL and does not need to be registered, it only needs to be redistributed with your application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[DisableTrace](#)

CFtpServer::EnumClients Method

```
INT EnumClients(  
    UINT *lpClients,  
    INT nMaxClients  
);
```

Return a list of active client connections established with the server.

Parameters

lpClients

Pointer to an array of unsigned integers which will contain client IDs that uniquely identifies each client when the method returns. If this parameter is NULL, then the method will return the number of active client connections established with the server.

nMaxClients

Maximum number of client IDs to be returned in the *lpClients* array. If the *lpClients* parameter is NULL, this parameter should have a value of zero.

Return Value

If the method succeeds, the return value is the number of active client connections to the server. If the method fails, the return value is FTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the *nMaxClients* parameter is less than the number of active client connections, the method will fail and the last error code will be set to the error ST_ERROR_BUFFER_TOO_SMALL. To dynamically determine the number of active connections, call the method with the *lpClients* parameter with a value of NULL, and the *nMaxClients* parameter with a value of zero.

Example

```
// Populate a listbox with all of the users connected to the server  
pListBox->ResetContent();  
  
INT nClients = pFtpServer->EnumClients();  
if (nClients > 0)  
{  
    UINT *pIdList = new UINT[nClients];  
  
    nClients = pFtpServer->EnumClients(pIdList, nClients);  
    if (nClients == FTP_ERROR)  
    {  
        // Unable to obtain list of connected clients  
        return;  
    }  
  
    for (INT nIndex = 0; nIndex < nClients; nIndex++)  
    {  
        CString strUserName;  
  
        if (pFtpServer->GetClientUserName(pIdList[nIndex], strUserName))  
            pListBox->AddString(strUserName);  
    }  
  
    // Free the memory allocated for the client IDs  
    delete pIdList;
```

```
}
```

Requirements

[GetClientAddress](#), [GetClientDirectory](#), [GetClientUserName](#)

CFtpServer::GetActiveClient Method

UINT GetActiveClient();

Return the client ID for the active client session associated with the current thread.

Parameters

None.

Return Value

If the method succeeds, the return value is the unique ID associated with the client session for the current thread. If there is no client session active on the current thread, the return value is zero.

Remarks

The **GetActiveClient** method is used to obtain the client ID associated with the current thread. This means this method will only return a client ID if it is called within an event handler or a method called by an event handler. If this method is called by a function that is not executing within the context of an event handler it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

[EnumClients](#)

CFtpServer::GetAddress Method

```
INT GetAddress(  
    UINT nClientId,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetAddress(  
    UINT nClientId,  
    CString& strAddress  
);
```

Return the IP address of the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszAddress

A pointer to a string buffer that will contain the server IP address, terminated with a null character. To accommodate both IPv4 and IPv6 addresses, this buffer should be at least 46 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If either the client ID is invalid, or the buffer is not large enough to store the complete address, the method will return a value of zero.

Remarks

This method will return the IP address assigned to the specified server as a printable string. If the *nClientId* parameter has a value of zero, this method will return the IP address assigned to the local system. If the FTP_SERVER_NATROUTER option was specified when the server was started, this method will return the external IP address assigned to the system. If the *nClientId* parameter specifies a valid client session, this method will return the IP address that the client used to establish the connection with the server. To determine the IP address assigned to the client, use the **GetClientAddress** method.

The format and length of IPv4 and IPv6 address strings are very different. An IPv4 address string looks like "192.168.0.20", while an IPv6 address string can look something like "fd7c:2f6a:4f4f:ba34::a32". If your application checks for the format of these address strings, it needs to be aware of the differences. You also need to make sure that you're providing enough space to display or store an address to avoid buffer overruns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetClientAddress](#), [GetName](#), [SetAddress](#)

CFtpServer::GetClientAccess Method

```
BOOL GetClientAccess(  
    UINT nClientId,  
    DWORD& dwUserAccess  
);
```

Return the access rights that have been granted to the client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more access rights for the client session. For a list of user access rights that can be granted to the client, see [User Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method can only be used with authenticated clients. If the client session has not been authenticated, the return value will be zero.

Remarks

The **GetClientAccess** method is used to obtain all of the access rights that are currently granted to an authenticated client session. The **EnableClientAccess** method can be used to enable or disable specific permissions, and the **SetClientAccess** method can change multiple access rights at once.

Example

```
DWORD dwUserAccess = 0;  
  
// Check if the client is a restricted user  
if (pFtpServer->GetClientAccess(nClientId, dwUserAccess))  
{  
    if (dwUserAccess & FTP_ACCESS_RESTRICTED)  
    {  
        std::cout << "Client authenticated as a restricted user\n";  
        return;  
    }  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

CFtpServer::GetClientAddress Method

```
INT GetClientAddress(  
    UINT nClientId,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetClientAddress(  
    UINT nClientId,  
    CString& strAddress  
);
```

Return the IP address of the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszAddress

A pointer to a string buffer that will contain the client IP address, terminated with a null character. To accommodate both IPv4 and IPv6 addresses, this buffer should be at least 46 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID is invalid, or the buffer is not large enough to store the complete address, the method will return a value of zero.

Remarks

The format and length of IPv4 and IPv6 address strings are very different. An IPv4 address string looks like "192.168.0.20", while an IPv6 address string can look something like "fd7c:2f6a:4f4f:ba34::a32". If your application checks for the format of these address strings, it needs to be aware of the differences. You also need to make sure that you're providing enough space to display or store an address to avoid buffer overruns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetClientDirectory](#), [GetClientUserName](#)

CFtpServer::GetClientCredentials Method

```
BOOL GetClientCredentials(  
    UINT nClientId,  
    LPFTPCLIENTCREDENTIALS lpCredentials  
);  
  
BOOL GetClientCredentials(  
    UINT nClientId,  
    CString& strUserName,  
    CString& strPassword  
);
```

Return the user credentials for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpCredentials

A pointer to an **FTPCLIENTCREDENTIALS** structure that will contain information about the user when the method returns. This parameter cannot be NULL.

strUserName

A string that will contain the user name when the method returns. This version of the method is only available for MFC and ATL based projects that define the **CString** object.

strPassword

A string that will contain the user password when the method returns. This version of the method is only available for MFC and ATL based projects that define the **CString** object.

Return Value

If the user credentials for the client session are available, the return value is non-zero. If the client ID does not specify a valid client session, or the client has not requested authentication, this method will return zero.

Remarks

The **GetClientCredentials** method is used to obtain the username and password that was provided by the client when it requested authentication. Typically this method is used in an event handler to validate the credentials provided by the client. If the credentials are considered valid, the event handler would then call the **AuthenticateClient** method to specify that the session has been authenticated.

If the default event handler is used, the **OnAuthenticate** method will be invoked with the user credentials passed to the handler as arguments.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CFtpServer::GetClientDirectory Method

```
INT GetClientDirectory(  
    UINT nClientId,  
    LPTSTR lpszDirectory,  
    INT nMaxLength  
);
```

```
INT GetClientDirectory(  
    UINT nClientId,  
    CString& strDirectory  
);
```

Returns the current working directory for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszDirectory

A pointer to a string buffer that will contain the current working directory for the specified client session, terminated with a null character. This buffer should be at least MAX_PATH characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be larger than zero or the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero.

Remarks

This method returns the full path to the current working directory for the specified client session. For example, if the server root directory is C:\ProgramData\MyServer and the current working directory for the client is /Research/Documents, this method will return C:\ProgramData\MyServer\Research\Documents as the current working directory for the client session.

It is important to note that the current working directory for client sessions is virtual, and does not reflect the current working directory for the server process. To change the current working directory for a client, use the **ChangeClientDirectory** method.

This method should only be used with client sessions that have been authenticated. Unauthenticated clients are not assigned a current working directory and this method will return zero, with the last error code set to ST_ERROR_AUTHENTICATION_REQUIRED.

To convert a full path to the virtual path for a specific client session, use the **GetClientVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[ChangeClientDirectory](#), [GetClientHomeDirectory](#), [GetClientVirtualPath](#),

CFtpServer::GetClientFileType Method

```
BOOL GetClientFileType(  
    UINT nClientId,  
    UINT& nFileType  
);
```

Return the current file type used for transfers by the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpnFileType

An unsigned integer value that will contain the current file type used by the client for data transfers.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **GetClientFileType** method will return the current file type that has been specified by the client sending the TYPE command to the server. The file type determines if there is any conversion performed on the data that is being exchanged between the client and server. The following file types are supported:

Value	Description
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those clients which use a different end-of-line character sequence, the text file has been converted to the local format which uses the carriage return (CR) and linefeed (LF) characters.
FILE_TYPE_IMAGE	The file is a binary file and no data conversion of any type has been performed on the file. This is the default file type for most data files and executable programs. If the client specified this file type when appending to a text file, the file will contain the end-of-line sequences used by its native operating system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::GetClientHomeDirectory Method

```
INT GetClientHomeDirectory(  
    UINT nClientId,  
    LPTSTR lpszDirectory,  
    INT nMaxLength  
);  
  
INT GetClientHomeDirectory(  
    UINT nClientId,  
    CString& strDirectory  
);
```

Returns the home directory for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszDirectory

A pointer to a string buffer that will contain the home directory for the specified client session, terminated with a null character. This buffer should be at least MAX_PATH characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be larger than zero or the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero.

Remarks

This method returns the full path to the home working directory assigned to the specified client session. This will be the same path to the home directory specified when the **AuthenticateClient** method was used to authenticate the client session. If a home directory was not explicitly assigned when the client was authenticated, then this method returns the default home directory that was created for the client, or the server root directory if the FTP_SERVER_MULTUSER option was not specified when the server was started.

This method should only be used with client sessions that have been authenticated. Unauthenticated clients are not assigned a home directory and this method will return zero, with the last error code set to ST_ERROR_AUTHENTICATION_REQUIRED.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetClientIdentity Method

```
INT GetClientIdentity(  
    UINT nClientId,  
    LPTSTR lpszIdentity,  
    INT nMaxLength  
);
```

```
INT GetClientIdentity(  
    UINT nClientId,  
    CString& strIdentity  
);
```

Return the identity of the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszIdentity

A pointer to a string buffer that will contain the identity of the client when the method returns, terminated with a null character. This parameter cannot be NULL. It is recommended that this buffer be at least 32 characters in length. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID is invalid, or the buffer is not large enough to store the complete path, the method will return a value of zero. If the client did not identify itself, this method will return zero.

Remarks

The **GetClientIdentity** method returns the string that the client used to identify itself to the server. The client may use either the CLNT or CSID command to identify itself. Although the CLNT command is considered to be deprecated, it is supported for backwards compatibility with older clients. The identity string does not have any standard format and is used for informational purposes only and does not affect the operation of the server in any way. Not all clients identify themselves, in which case this method will return zero and the *lpszIdentity* string buffer will be set to an empty string.

If the client does identify itself, it typically uses the name of the client application that was used to establish the connection. The application may choose to assign an identity to a client session for its own internal purposes using the **SetClientIdentity** method, regardless of whether the client identifies itself.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetIdentity](#), [SetClientIdentity](#), [SetIdentity](#)

CFtpServer::GetClientIdleTime Method

```
UINT GetClientIdleTime(  
    UINT nClientId,  
    UINT *lpnElapsed  
);
```

Return the idle timeout period for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpnElapsed

An optional pointer to an unsigned integer value that will contain the number of seconds the client session has been idle. This parameter may be NULL or omitted if this information is not required.

Return Value

If the method succeeds, the return value is client idle timeout period in seconds. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **GetClientIdleTime** method will return the number of seconds that the client may remain idle before being automatically disconnected by the server. The idle time of a client session is based on the last time a command was issued to the server or when a file data transfer completed. The server will never disconnect a client that is in the process of uploading or downloading a file, regardless of the idle timeout period.

The default idle timeout period for a client is 900 seconds (15 minutes), however the server can be configured to use a different value and individual clients can request the timeout period be changed by sending the IDLE command to the server. For a client to be able to change its own timeout period, it must be granted the FTP_ACCESS_IDLE permission. The minimum timeout period for a client is 60 seconds, the maximum is 7200 seconds (2 hours). An application can change the timeout period for a specific client session using the **SetClientIdleTime** method.

It is important to note that the idle timeout period only affects authenticated clients. Unauthenticated clients use a different internal timer that limits the amount of time they can remain connected to the server before successfully authenticating with a valid username and password. By default, the authentication timeout period is 60 seconds and is set when the server is started; it cannot be changed for an individual client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::GetClientLocalPath Method

```
INT GetClientLocalPath(  
    UINT nClientId,  
    LPCTSTR lpszVirtualPath,  
    LPTSTR lpszLocalPath,  
    INT nMaxLength,  
);
```

```
INT GetClientLocalPath(  
    UINT nClientId,  
    LPCTSTR lpszVirtualPath,  
    CString& strLocalPath  
);
```

Return the full local path for a virtual filename or directory on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszVirtualPath

A pointer to a string that specifies an virtual path on the server. This parameter cannot be NULL.

lpszLocalPath

A pointer to a string buffer that will contain the full local path, terminated with a null-character. This buffer should be at least MAX_PATH characters to accommodate the complete path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the string buffer is not large enough to contain the complete path, this method will return zero and the last error code will be set to ST_ERROR_BUFFER_TOO_SMALL.

Remarks

The **GetClientLocalPath** method takes a virtual path and returns the full path to the specified file or directory on the local system. The virtual path may be absolute or relative to the current working directory for the client session. This method will recognize a tilde at the beginning of the path to specify the client home directory.

To obtain the virtual path for a local file or directory, use the **GetClientVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientVirtualPath](#)

CFtpServer::GetClientServer Method

```
HSERVER HttpGetClientServer(  
    UINT nClientId  
);
```

The **GetClientServer** method returns a handle to the server that created the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is the handle to the server that created the client session. If the method fails, the return value is INVALID_SERVER. To get extended error information, call the **GetLastError** method.

Remarks

The **GetClientServer** method returns the handle to the server that created the client session and is typically used within a notification message handler. If the server is in the process of shutting down, or the client session thread is terminating, this method will fail and return INVALID_SERVER indicating that the session ID is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h.

Import Library: csftsv11.lib

See Also

[AsyncNotify](#)

CFtpServer::GetClientThreadId Method

```
DWORD GetClientThreadId(  
    UINT nClientId  
);
```

Returns the thread ID associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is a thread ID. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **GetClientThreadId** method returns a thread ID that can be used to identify the thread that is managing the client session. The thread ID can be used with other Windows API functions such as **OpenThread**. Exercise caution when using thread-related functions, interfering with the normal operation of the thread can have unexpected results. You should never use this method to obtain a thread handle and then call the **TerminateThread** function to terminate a client session. This will prevent the thread from releasing the resources that were allocated for the session and can leave the server in an unstable state. To terminate a client session, use the **DisconnectClient** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

```
INT GetClientUserName(  
    UINT nClientId,  
    LPTSTR lpszUserName,  
    INT nMaxLength  
);
```

```
INT GetClientUserName(  
    UINT nClientId,  
    CString& strUserName  
);
```

Return the user name associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

strUserName

A pointer to a string buffer that will contain the user name associated with the client session. This buffer must be large enough to store the complete user name, including the terminating null character. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, or the client has not authenticated itself, the method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AuthenticateClient](#), [GetClientAccess](#), [GetClientHomeDirectory](#)

CFtpServer::GetClientVirtualPath Method

```
INT GetClientVirtualPath(  
    UINT nClientId,  
    LPCTSTR lpszLocalPath,  
    LPTSTR lpszVirtualPath,  
    INT nMaxLength,  
);
```

```
INT GetClientVirtualPath(  
    UINT nClientId,  
    LPCTSTR lpszLocalPath,  
    CString& strVirtualPath  
);
```

Return the virtual path for a local file on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszLocalPath

A pointer to a string that specifies an absolute path on the local system. This parameter cannot be NULL.

lpszVirtualPath

A pointer to a string buffer that will contain the virtual path, terminated with a null-character. This buffer should be at least MAX_PATH characters to accommodate the complete path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the string buffer is not large enough to contain the complete path, this method will return zero and the last error code will be set to ST_ERROR_BUFFER_TOO_SMALL.

Remarks

A virtual path for the client is either relative to the server root directory, or the client home directory if the client was authenticated as a restricted user. These virtual paths are what the client will see as an absolute path on the server. For example, if the server was configured to use "C:\ProgramData\MyServer" as the root directory, and the *lpszLocalPath* parameter was specified as "C:\ProgramData\MyServer\Documents\Research", this method would return the virtual path to that directory as "/Documents/Research".

If the client session was authenticated as a restricted user, then the virtual path is always relative to the client home directory instead of the server root directory. This is because restricted users are isolated to their own home directory and any subdirectories. For example, if restricted user "John" has a home directory of "C:\ProgramData\MyServer\Users\John" and the *lpszLocalPath* parameter was specified as "C:\ProgramData\MyServer\Users\John\Accounting\Projections.pdf" this method would return the

virtual path as `"/Accounting/Projections.pdf"`.

If the ***lpzLocalPath*** parameter specifies a file or directory outside of the server root directory, this method will return zero and the last error code will be set to `ST_ERROR_INVALID_FILE_NAME`. This method can only be used with authenticated clients. If the ***nClientId*** parameter specifies a client session that has not been authenticated, this method will return zero and the last error code will be `ST_ERROR_AUTHENTICATION_REQUIRED`.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csftsv11.lib`

CFtpServer::GetCommandFile Method

```
INT GetCommandFile(  
    UINT nClientId,  
    LPTSTR lpszFileName,  
    INT nMaxLength  
);
```

```
INT GetCommandFile(  
    UINT nClientId,  
    CString& strFileName  
);
```

Get the full path to the local file name or directory specified by the client

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string buffer that will contain the full path to a file name or directory specified by the client when it issued a command. The string buffer will be null terminated and must be large enough to store the complete file path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. It is recommended that the buffer be at least MAX_PATH characters in size. If the maximum length specified is smaller than the actual length of the full path, this method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code is returned as a value of zero, this means that the command issued by the client accepts a file name as an argument, but the client did not specify one.

Remarks

The **GetCommandFile** method is used to obtain the full path to a local file name or directory specified by the client as an argument to a standard FTP command. For example, if the client sends the RETR command to the server, this method will return the complete path to the local file that the client wants to download. This method will only work with those standard commands that perform some action on a file or directory.

This method should always be used to obtain the file name for a command that performs a file or directory operation. The **GetCommandParam** method will return the actual command parameter, but the file name will typically be relative to the user home directory or server root directory, and cannot be passed directly to a Windows API function. The **GetCommandFile** method normalizes the path provided by the client and ensures that it specifies a file or directory name in the correct location.

To change the file or directory name that is the target of the current command, use the **SetCommandFile** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientDirectory](#), [GetClientHomeDirectory](#), [GetCommandLine](#), [GetCommandParam](#),
[SetCommandFile](#)

CFtpServer::GetCommandLine Method

```
INT GetCommandLine(  
    UINT nClientId,  
    LPTSTR lpszCmdLine,  
    INT nMaxLength  
);  
  
INT GetCommandLine(  
    UINT nClientId,  
    CString& strCmdLine  
);
```

Return the complete command line issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCmdLine

A pointer to a string buffer that will contain the command, including all arguments. The string buffer will be null terminated and must be large enough to store the complete command line. If this parameter is NULL, the method will return the length of the command line. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. The internal limit on the maximum length of a command is 1024 characters. If the maximum length specified is smaller than the actual length of the complete command, this method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code has a value of zero then no command has been issued by the client.

Remarks

The **GetCommandLine** method is used to obtain the command that was issued by the client, and is commonly used inside the **OnCommand** and **OnResult** event handlers to pre-process and post-process client commands, respectively. When the method returns, the string buffer provided by the caller will contain the complete command, including all command parameters. Any extraneous whitespace will be removed, however quoted parameters will be retained as-is.

To obtain a specific parameter to a command, use the **GetCommandParam** method. The **GetCommandParamCount** method will return the number of command parameters that were provided by the client. If the command sent by the client is used to perform an action on a file or directory, the **GetCommandFile** method should be called to obtain the full path to the specified file rather than using the value of the command parameter.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#), [GetCommandParam](#), [OnCommand](#), [OnResult](#)

CFtpServer::GetCommandName Method

```
INT GetCommandName
    UINT nClientId,
    LPTSTR lpszCommand,
    INT nMaxLength
);

INT GetCommandName
    UINT nClientId,
    CString& strCommand
);
```

Return the name of the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string buffer that will contain the command name. The string buffer will be null terminated and must be large enough to store the complete command name. If this parameter is NULL, the method will only return the length of the current command in characters, not including the terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. If the maximum length specified is smaller than the actual length of the parameter, this method will fail. If the *lpszCommand* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code is returned as a value of zero, this means that no command has been issued by the client.

Remarks

The **GetCommandName** method is used to obtain the name of the last command that was issued by the client. The command name returned by this method will always be capitalized, regardless of how it was sent by the client. This method is typically used inside the **OnCommand** and **OnResult** event handlers to pre-process and post-process client commands, respectively.

The **GetCommandParam** method can be used to return the value of individual command parameters specified by the client. The **GetComandLine** method can be used to obtain the complete command line issued by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#), [GetCommandLine](#), [GetCommandParam](#), [OnCommand](#), [OnResult](#)

CFtpServer::GetCommandParam Method

```
INT GetCommandParam
    UINT nClientId,
    INT nParam,
    LPTSTR lpszParam,
    INT nMaxLength
);
```

```
INT GetCommandParam
    UINT nClientId,
    INT nParam,
    CString& strParam
);
```

Return the value of the specified command parameter from the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nParam

An integer value which specifies the command parameter. A value of zero specifies the command itself, while values greater than zero specify a particular parameter. This method will fail if this value is less than zero or greater than the number of parameters available.

lpszParam

A pointer to a string buffer that will contain the command parameter. The string buffer will be null terminated and must be large enough to store the complete parameter value. If this parameter is NULL, the method will only return the length of the specified parameter in characters, not including the terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. The internal limit on the maximum length of a command is 1024 characters. If the maximum length specified is smaller than the actual length of the parameter, this method will fail. If the *lpszParam* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code is returned as a value of zero, this means that no command has been issued by the client.

Remarks

The **GetCommandParam** method is used to obtain a specific parameter for the last command that was issued by the client. If the parameter was surrounded in quotes, those quotes will be included in the value returned by this method. This method is typically used inside the **OnCommand** and **OnResult** event handlers to pre-process and post-process client commands, respectively.

The **GetCommandParamCount** method will return the number of command parameters that were provided by the client. If the command sent by the client is used to perform an action on a file or directory, the **GetCommandFile** method should be called to obtain the full path to the specified file

rather than using the value of the command parameter. To obtain the complete command line, use the **GetCommandLine** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#), [GetCommandLine](#), [GetCommandName](#), [GetCommandParamCount](#), [OnCommand](#), [OnResult](#)

CFtpServer::GetCommandParamCount Method

```
INT GetCommandParamCount  
    UINT nClientId  
);
```

Return the number of command parameters for the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

An integer value which specifies the number of parameters that were specified in the last command issued by the client. If the command did not include any parameters, this method will return zero. If the client has not issued a command, or the client session ID is invalid, this method will return -1.

Remarks

The **GetCommandParamCount** method is used to determine the number of parameters specified in the last client command, and the maximum value that may be passed as the parameter index to the **GetCommandParam** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::GetCommandResult Method

```
INT GetCommandResult(  
    UINT nClientId,  
    LPTSTR lpszResult,  
    INT nMaxLength  
);  
  
INT GetCommandResult(  
    UINT nClientId,  
    CString& strResult  
);
```

Return the result code and description for the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszResult

A pointer to a string buffer that will contain the description of the result code. The string buffer will be null terminated up to the maximum number of characters specified by the caller. This parameter can be NULL if this information is not required. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. If the *lpszResult* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the result code for the last command issued by the client. A return value of zero indicates that the command has not completed and there is no result code available.

Remarks

The **GetCommandResult** method is used to determine the result of the last command that was issued by the client and is typically called in the **OnResult** event handler. This method should only be called after a command has been processed or the **SendResponse** method has been called.

The result code is a three-digit integer value that indicates the success or failure of a command. Whenever a client sends a command to the server, the server must respond with this numeric code, and optionally a text message that further describes the result. The text message may be a single line, or it may span multiple lines, with each line of text terminated by a carriage return and linefeed. Result codes are generally broken down into the following categories:

Result Code	Description
100-199	Result codes in this range indicate that the requested action is being initiated, and the client should expect another reply from the server before proceeding. This is normally used with file transfers, indicating to the client that the data transfer has started.
200-299	Result codes in this range indicate that the server has successfully completed the requested action. One exception is the 202 result code which indicates that the command is not implemented, but the client should not consider this to be an error condition.

300-399	Result codes in this range indicate that the requested action cannot complete until additional information is provided to the server. This is normally used with commands that require a specific sequence to complete. For example, the server will send the 331 result code in response to the USER command, which tells the client that it must send the PASS command to complete the authentication process.
400-499	Result codes in this range indicate that the requested action did not take place, but the error condition is temporary and may be attempted again. This error response is usually the result of a failed authentication attempt or a file transfer that could not complete.
500-599	Result codes in this range indicate that the requested action did not take place and the failure is permanent. The client should not attempt to send the command again. This error response is usually the result of an invalid command name, a syntax error or the client not having the appropriate access rights to a resource.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

[SendResponse](#), [OnResult](#)

CFtpServer::GetCommandUsage Method

```
UINT GetCommandUsage(  
    LPCTSTR lpszCommand  
);
```

Return the number of times a specific command has been issued by all clients.

Parameters

lpszCommand

A pointer to a string that specifies a command name. The name is not case-sensitive, but must match a valid server command exactly. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is the number of times the command has been issued by all clients since the server was started. If the command name is invalid, or the command has never been issued, the return value will be zero.

Remarks

The command name provided to this method must match the commands defined in RFC 959 or related protocol standards. It is important to distinguish between commands recognized by an FTP server and the commands that client programs may use. For example, the standard Windows FTP command line program provides commands such as GET and PUT to download and upload files. However, those are not the actual commands sent to a server. Instead, the corresponding server commands issued by a client application would be RETR (retrieve) and STOR (store). Refer to [File Transfer Protocol Commands](#) for a complete list of server commands.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::GetDirectory Method

```
INT GetDirectory(  
    LPTSTR lpszDirectory,  
    INT nMaxLength  
);  
  
INT GetDirectory(  
    CString& strDirectory  
);
```

Return the full path to the root directory assigned to the specified server.

Parameters

lpszDirectory

A pointer to a string buffer that will contain the server root directory, terminated with a null character. It is recommended that this buffer be at least MAX_PATH characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete path, the method will return a value of zero.

Remarks

The **GetDirectory** method will return the full path to the root directory assigned to the server instance. The root directory may be specified as part of the server configuration, or if no directory is specified by the application, the current working directory will be used and this method can be used to obtain the full path to the directory. When the application specifies a root directory, it may use environment variables such as %AppData% in the path. This method will return the fully resolved path name, with all environment variables expanded.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetIdentity](#), [GetName](#), [SetDirectory](#)

CFtpServer::GetHandle Method

HSERVER GetHandle();

The **GetHandle** method returns the server handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the server handle associated with the current instance of the class object. If the server is inactive, the value INVALID_SERVER will be returned.

Remarks

This method is used to obtain the server handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

[IsInitialized](#)

CFtpServer::GetIdentity Method

```
INT GetIdentity(  
    LPTSTR lpszIdentity,  
    INT nMaxLength  
);  
  
INT GetIdentity(  
    CString& strIdentity  
);
```

Return the identity of the specified server.

Parameters

lpszIdentity

A pointer to a string buffer that will contain the identity of the server when the method returns, terminated with a null character. This parameter cannot be NULL. It is recommended that this buffer be at least 32 characters in length. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete path, the method will return a value of zero.

Remarks

The **GetIdentity** method returns the identity string that was specified as part of the server configuration. It is used for informational purposes only and does not affect the operation of the server. Typically the string specifies the name of the application and a version number, and is displayed whenever a client establishes its initial connection to the server. The **SetIdentity** method can be used to change the identity string associated with the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetLastError Method

```
DWORD GetLastError(  
    LPTSTR lpszError,  
    INT nMaxLength  
);  
  
DWORD GetLastError(  
    CString& strError  
);  
  
DWORD GetLastError();
```

Return the last server error code and a description of the error.

Parameters

lpszError

A pointer to a string buffer that will contain a description of the error. If the error description is not needed, this parameter may be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the error string buffer, including the terminating null character. If the *lpszError* parameter is NULL, this value should be zero.

Return Value

An unsigned integer value that specifies the last error that occurred. A value of zero indicates that there was no error.

Remarks

Error codes are unsigned 32-bit values which are private to each server. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods clear the last error code when they succeed.

It is important to note that the error codes returned by this method are different than the command result codes that are defined in RFC 959, the standard protocol specification for FTP. This method is used to determine reason that an API function has failed, and should not be used to determine if a command issued by the client was successful. The **SendResponse** method is used to send result codes to the client, and the **GetCommandResult** method can be used to determine the result of the last command sent by the client.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Failure is typically indicated by a return value such as FALSE, NULL, INVALID_SERVER or FTP_ERROR. Those methods which clear the last error code when they succeed are noted on their reference page.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetLogFile Method

```
BOOL GetLogFile(
    UINT *lpnLogFormat,
    UINT *lpnLogLevel,
    LPTSTR lpszFileName,
    INT nMaxLength
);

BOOL GetLogFile(
    UINT *lpnLogFormat,
    UINT *lpnLogLevel,
    CString& strFileName
);

BOOL GetLogFile(
    CString& strFileName
);
```

Return the current log file format and the full path to the file.

Parameters

lpnLogFormat

A pointer to an integer value that will contain the log file format being used when the method returns. If this information is not needed, this parameter may be NULL. The following formats are supported:

Value	Description
FTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
FTP_LOGFILE_COMMON	This value specifies that the log file should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about file transfers.
FTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session.

lpnLogLevel

A pointer to an integer value that will contain the level of detail the server uses when generating the log file. The minimum value is 1 and the maximum value is 10. If this information is not needed, this parameter may be NULL.

lpszFileName

A pointer to a string buffer that will contain the full path to the log file. This parameter may be NULL if this information is not required. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the file name string, including the terminating null character. If the *lpszFileName* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the current log file format. Refer to the **FTPSERVERCONFIG** structure definition for a list of supported log file formats. If logging has not been enabled, this method will return a value of zero.

Remarks

If the server is configured with logging enabled, but a log file name is not explicitly provided, then the server will automatically generate one. This method can be used to get the full path to the current log file along with the format that is being used to record client session data. Normally the log file is held open by the server thread while it is active, however you can call the **RenameServerLogFile** method to explicitly rename or delete the log file.

To change the name of the log file, the log file format or level of detail, use the **SetLogFile** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[RenameServerLogFile](#), [SetLogFile](#)

GetMemoryUsage Method

```
SIZE_T GetMemoryUsage();
```

Return the amount of memory allocated for the server and all client sessions.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero and specifies the amount of memory allocated by the server. If the server is inactive or cannot be locked, the return value is zero. Call the **GetLastError** method to determine the cause of the failure.

Remarks

This method returns the amount of memory allocated by the server and all active client sessions. It enumerates all of memory allocations made by the server process and client session threads and returns the total number of bytes allocated for the server process. This value reflects the amount of memory explicitly allocated by this library and does not reflect the total working set size of the process, or memory allocated by any other libraries. To determine the working set size for the process, refer to the Win32 **GetProcessWorkingSetSize** and **GetProcessMemoryInfo** functions.

This method forces the server into a locked state, and all client sessions will block until the method returns. Because this method enumerates all heaps allocated for the server process, it can be an expensive operation, particularly when there are a large number of active clients connected to the server. Frequent use of this method can significantly degrade the performance of the server. It is primarily intended for use as a debugging tool to determine if memory usage is the result of an increase in active client sessions. If the value returned by the method remains reasonably constant, but the amount of memory allocated for the process continues to grow, it could indicate a memory leak in some other area of the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetStackSize](#), [SetStackSize](#)

CFtpServer::GetName Method

```
INT GetName(  
    UINT nClientId,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
INT GetName(  
    UINT nClientId,  
    CString& strHostName  
);
```

Return the host name assigned to the specified server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszHostName

A pointer to a string buffer that will contain the server host name, terminated with a null character. It is recommended that this buffer be at least 64 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID is invalid or the buffer is not large enough to store the complete hostname, the method will return a value of zero.

Remarks

This method will return the host name assigned to the specified server. If the *nClientId* parameter has a value of zero, the method will return the default host name that was specified as part of the server configuration. If no host name was explicitly assigned to the server, then it will return the local system name. If the *nClientId* parameter specifies a client session, then it this method will return the host name that the client used to establish the connection. If the client sends the HOST command to the server, this method will return the host name provided by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

[SetOptions](#)

CFtpServer::GetPriority Method

INT GetPriority();

Return the current priority assigned to the specified server.

Parameters

None.

Return Value

If the method succeeds, the return value is the priority for the specified server. If the method fails, the return value is FTP_PRIORITY_INVALID. To get extended error information, call the **GetLastError** method.

Remarks

The **GetPriority** method can be used to determine the current priority assigned to the server. It will return one of the following values:

Value	Description
FTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the server. It is typically used with lightweight services running in the background that are designed for few client connections. The server thread will be assigned a lower scheduling priority and will be frequently forced to yield execution to other threads.
FTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the server and meters the processor utilization for the server thread. The server thread will be assigned a lower scheduling priority and will occasionally be forced to yield execution to other threads.
FTP_PRIORITY_NORMAL	The default priority which balances resource and processor utilization. This is the priority that is initially assigned to the server when it is started, and it is recommended that most applications use this priority.
FTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the server and the thread will be given higher scheduling priority. It is not recommended that this priority be used on a system with a single processor.
FTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization. The server thread will be given higher scheduling priority and will be more responsive to client connection requests. It is not recommended that this priority be used on a system with a single processor.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h.

[SetPriority](#), [Start](#)

CFtpServer::GetProgramExitCode Method

```
BOOL GetProgramExitCode(  
    UINT nClientId,  
    DWORD& dwExitCode  
);
```

Return the exit code of the last program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwExitCode

An unsigned integer that will contain the program exit code when the method returns.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **GetProgramExitCode** method returns the exit code of a registered program that was executed by the client using the SITE EXEC command. By convention, most programs return an exit code in the range of 0-255, with an exit code of zero indicating success. The exit code is commonly used by custom programs to communicate status information back to the server application.

Permission to use the SITE EXEC is not granted to authenticated users by default, and is limited to only those programs which are explicitly registered with the server. Exercise caution when allowing a client to execute a program on the server because this can expose the server to significant security risks. The programs that are registered for use with the SITE EXEC command should be thoroughly tested before being deployed on the server and should only be console programs that write to standard output.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[GetProgramName](#), [GetProgramOutput](#), [RegisterProgram](#)

CFtpServer::GetProgramName Method

```
INT GetProgramName(  
    UINT nClientId,  
    LPTSTR lpszProgramName,  
    INT nMaxLength  
);  
  
INT GetProgramName(  
    UINT nClientId,  
    CString& strProgramName  
);
```

Return the name of the last program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszProgramName

A pointer to a string buffer that will contain the name of the last program executed by the client.

This parameter cannot be NULL and should be at least 32 characters in size. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This parameter must have a value greater than zero.

Return Value

If the method succeeds, the return value is the length of the command name. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed any programs, this method will return zero.

Remarks

The **GetProgramName** method returns the name of the last program that was executed by the client using the SITE EXEC command. The name that is returned is the alias assigned to the program, not the full path to the executable file. The server application would typically use this method in an event handler when processing the FTP_CLIENT_EXECUTE event to determine which program has been executed on behalf of the client. The **GetProgramExitCode** method will return the program's exit code and the **GetProgramOutput** method can be used to obtain a copy of the output generated by the program.

Permission to use the SITE EXEC is not granted to authenticated users by default, and is limited to only those programs which are explicitly registered with the server. Exercise caution when allowing a client to execute a program on the server because this can expose the server to significant security risks. The programs that are registered for use with the SITE EXEC command should be thoroughly tested before being deployed on the server and should only be console programs that write to standard output.

CFtpServer::GetProgramOutput Method

```
DWORD GetProgramOutput(  
    UINT nClientId,  
    LPBYTE lpBuffer,  
    DWORD dwBufferSize  
);
```

Return a copy of the standard output from the last program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpBuffer

A pointer to a buffer that will contain the output from the last program executed by the client. If this parameter is NULL, the method will return the number of bytes of data that was output by the program. Note that this output is not null terminated.

dwBufferSize

The maximum number of bytes that can be copied into the buffer. If the *lpBuffer* parameter is NULL, this value should be zero.

Return Value

If the method succeeds, the return value is the number of bytes copied into the specified buffer. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed any programs, the return value will be zero.

Remarks

The **GetProgramOutput** method is used to obtain a copy of the output generated by the program executed using the SITE EXEC command. To determine the number of bytes of output available to read, call this method with the *lpBuffer* parameter as NULL and the *dwBufferSize* parameter with a value of zero. The return value will be the number of bytes of data that was output by the program. It should be noted that for Unicode builds, the buffer is a byte array, not an array of characters, and will not be null terminated.

This method returns the raw output from the command which may contain escape sequences, control characters and embedded nulls. When the application processes the output returned by this method, it should never coerce the buffer pointer to an LPTSTR value because there is no guarantee that the data will be null-terminated. To obtain the output from the command as a string, use the **GetProgramText** method.

Example

```
LPBYTE lpBuffer = NULL; // A pointer to the output buffer  
DWORD cbBuffer = 0;     // Number of bytes in the output buffer  
  
// Determine the number of bytes in the output buffer  
cbBuffer = pFtpServer->GetProgramOutput(nClientId, NULL, 0);  
  
if (cbBuffer > 0)  
{  
    // Allocate memory for the buffer  
    lpBuffer = new BYTE[cbBuffer + 1];
```

```
        // Copy the program output to the buffer
        cbBuffer = pFtpServer->GetProgramOutput(nClientId, lpBuffer, cbBuffer + 1);
    }

    // Free the memory allocated for the buffer when finished
    if (lpBuffer != NULL)
    {
        delete lpBuffer;
        lpBuffer = NULL;
        cbBuffer = 0;
    }
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

CFtpServer::GetProgramText Method

```
INT GetProgramText(  
    UINT nClientId,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

```
INT GetProgramText(  
    UINT nClientId,  
    CString& strBuffer  
);
```

Return a copy of the standard output from the last program in a string buffer.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszBuffer

A pointer to a buffer that will contain the output from the last program executed by the client as a string. If this parameter is NULL, the method will return the number of bytes of characters that was output by the program, not including a terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

The maximum number of bytes that can be copied into the buffer. If the *lpszBuffer* parameter is NULL, this value should be zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the specified string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed any programs, the return value will be zero.

Remarks

The **GetProgramText** method is used to obtain a copy of the output generated by the program executed using the SITE EXEC command. To determine the number of characters of output available to read, call this method with the *lpszBuffer* parameter as NULL and the *nMaxLength* parameter with a value of zero. The return value will be the number of characters that were output by the program. If the application dynamically allocates the string buffer, make sure that it allocates an extra character for the terminating null character.

This method will only return textual output from the command and any non-printable control characters and the escape character will be replaced with a space. To obtain the unfiltered output from the last command that was executed, use the **GetProgramOutput** method.

Example

```
CString strBuffer;  
  
if (pFtpServer->GetProgramText(nClientId, strBuffer) > 0)  
    pEditCtrl->SetWindowText(strBuffer);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetRenamedFile Method

```
INT GetRenamedFile(  
    UINT nClientId,  
    LPTSTR lpszFileName,  
    INT nMaxLength  
);
```

```
INT GetRenamedFile(  
    UINT nClientId,  
    CString& strFileName  
);
```

Return the original name of a file being renamed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string buffer that will contain the full path of the last file or directory that was renamed. It is recommended that this buffer be at least MAX_PATH characters in size. The value of this parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null characters. This parameter must have a value larger than zero.

Return Value

If the method succeeds, the return value is the length of the file or directory path, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the client has not renamed a file or directory, this method will return zero.

Remarks

When a client wishes to rename a file or directory, it must send two commands in sequence to the server. The first command is RNFR (rename from) which specifies the original name of the file or directory to be renamed. The second command is RNTD (rename to) and must be sent immediately after the RNFR command and specifies the new name for the file or directory. The **GetRenamedFile** method will return the full path of the local file or directory that was specified by the RNFR command. Typically this method is used by an event handler that processes the **OnCommand** event to determine the original path name.

This method is only guaranteed to return a meaningful value when called within the context of the **OnCommand** event handler. Calling this method outside of the event handler will return the path of the last renamed file, but there is no way to determine at what point the client issued the command to rename a file or directory. To obtain the new file or directory name, the **GetCommandFile** method should be called from within the event handler.

The RNFR and RNTD commands can also be used to move a file or directory to a new location. For example, they could be used to move a file from one directory to another. An application should never make the assumption that the paths of the original and new file will be the same.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetStackSize Method

DWORD GetStackSize();

Return the initial size of the stack allocated for threads created by the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the amount of memory that will be allocated for the stack in bytes. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **GetStackSize** method returns the initial amount of memory that is committed to the stack for each thread created by the server. By default, the stack size for each thread is set to 256K for 32-bit processes and 512K for 64-bit processes.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftsv11.lib

See Also

[SetStackSize](#), [Start](#)

CFtpServer::GetTransferInfo Method

```
BOOL GetTransferInfo(  
    UINT nClientId,  
    LPFTPSEVERTRANSFER lpTransferInfo  
);
```

Return information about the current file transfer for the client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpTransferInfo

A pointer to an **FTPSEVERTRANSFER** structure that will contain information about the last file transfer. This parameter cannot be NULL, and the *dwSize* member of the structure must be initialized to specify the structure size prior to calling this method.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method should only be called after the client has issued the APPE, RETR, STOR or STOU commands to initiate a file transfer, otherwise the return value will be zero.

Remarks

The **GetTransferInfo** method is used to obtain information about the last file transfer that was performed by the client. This method is typically called within an event handler to determine how many bytes of data were transferred, the type of file and the full path to the file on the local system.

If the default event handler is used, the **OnDownload** and **OnUpload** methods will be invoked with information about the transfer passed as arguments to the handler.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::GetUuid Method

```
INT GetUuid(  
    LPTSTR lpszHostUuid,  
    INT nMaxLength  
);  
  
INT GetUuidString(  
    CString& strHostUuid  
);
```

Return the UUID assigned to the server as a printable string.

Parameters

lpszHostUuid

A pointer to a string buffer that will contain the server UUID, terminated with a null character. It is recommended that this buffer be at least 40 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete UUID string, the method will return a value of zero.

Remarks

The **GetUuid** method returns the Universally Unique Identifier (UUID) that has been assigned to the server. The UUID may either be generated by the application and assigned as part of the server configuration, or an ephemeral UUID may be automatically generated when the server is started.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::IsActive Method

BOOL IsActive();

Determine if the server has been started.

Return Value

This method returns a non-zero value if the server has been started. If the server is stopped this method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[CFtpServer](#), [IsListening](#), [Start](#), [Stop](#)

CFtpServer::IsClientAnonymous Method

```
BOOL IsClientAnonymous(  
    UINT nClientId  
);
```

Determine if the specified client has authenticated as an anonymous user.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the client session has been authenticated, this method will return a non-zero value, otherwise it will return zero. If the client ID is valid, and the client session has been authenticated, this method will clear the last error code.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::IsClientAuthenticated Method

```
BOOL IsClientAuthenticated(  
    UINT nClientId  
);
```

Determine if the specified client session has been authenticated.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the client session has been authenticated, this method will return a non-zero value, otherwise it will return zero. If the client ID is valid, this method will clear the last error code.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

[AuthenticateClient](#), [GetClientCredentials](#), [IsClientAnonymous](#)

CFtpServer::IsCommandEnabled Method

```
BOOL IsCommandEnabled(  
    LPCTSTR lpszCommand  
);
```

Determine if a specific server command has been enabled or disabled.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command. The command name is not case-sensitive, but the value must otherwise match the exact command name. Partial matches are not recognized by this method. This parameter cannot be NULL.

Return Value

If the command is enabled, this method will return a non-zero value. If the command is disabled or the command name does not match a supported command, this method will return zero.

Remarks

The **IsCommandEnabled** method is used to determine whether a specific command is enabled. Typically this method is used in an event handler to make sure the command issued by a client is recognized by the server and enabled for use. Commands can be enabled using the **EnableCommand** method and disabled using the **DisableCommand** method.

This method does not account for the permissions granted to a specific client session. Clients are assigned access rights when they are authenticated using the **AuthenticateClient** method, and certain commands can be limited by the permissions granted to the client. For example, even though the STOR command is enabled, a client must have the FTP_ACCESS_WRITE permission to use the command to upload a file to the server. For a list of access rights, see [User Access Constants](#).

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AuthenticateClient](#), [DisableCommand](#), [EnableCommand](#), [GetCommandName](#)

CFtpServer::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftpv11.lib

See Also

[CFtpServer](#)

CFtpServer::IsListening Method

BOOL IsListening();

The **IsListening** method returns whether or not the server is listening for client connections.

Return Value

This method returns a non-zero value if the server has been started and is listening for client connections. If the server is stopped or has been suspended this method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftpv11.lib

See Also

[CFtpServer](#), [Start](#), [Stop](#)

CFtpServer::PreProcessEvent Method

```
virtual LONG PreProcessEvent(  
    HSERVER hServer,  
    UINT nClientId,  
    UINT nEventId,  
    DWORD dwError,  
    BOOL& bHandled  
);
```

A virtual method that is invoked for each event generated by the server.

Parameters

hServer

The server handle. The application should treat this as an opaque value that is only valid as long as the server is active. This value should not be stored by the application and the handle value will change if the server is restarted.

nClientId

An unsigned integer which uniquely identifies the client that has issued a request to the server. This value is guaranteed to be unique to the client session throughout the life of the server and is never reused. The application should never make assumptions about the order in which IDs are allocated to the client sessions.

nEventId

An unsigned integer which specifies which event occurred. For a list of events, see [Server Event Constants](#).

dwError

An unsigned integer which specifies any error that occurred. If no error occurred, then this parameter will be zero.

bHandled

An integer which specifies if the event has been handled by the application. If this parameter is set to a non-zero value, the default event handler will not be invoked for the event.

Return Value

The method should return a value of zero to indicate that the default event handler should be invoked for the event. If the method returns a non-zero value, this value is passed back to the event dispatcher and the default handler will not be invoked.

Remarks

The **PreProcessEvent** method is invoked for each event that is generated, prior to the default handler for that event. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

CFtpServer::RegisterProgram Method

```
BOOL RegisterProgram(  
    LPCTSTR lpszCommandName,  
    LPCTSTR lpszProgramFile  
);
```

```
BOOL RegisterProgram(  
    LPCTSTR lpszCommandName,  
    LPCTSTR lpszProgramFile,  
    LPCTSTR lpszParameters,  
    LPCTSTR lpszDirectory,  
);
```

Register a program for use with the SITE EXEC command.

Parameters

lpszCommandName

A pointer to a string which specifies the name of the site specific command. This is the name that is passed to the SITE EXEC command and does not need to match the actual name of the executable file on the local system. The maximum length of the command name is 32 characters. This parameter cannot be NULL.

lpszProgramFile

A pointer to a string that specifies the full path to the executable program. This parameter cannot be NULL.

lpszParameters

A pointer to a string that specifies additional parameters for the program. If the program does not require any command line parameters, this value may be NULL or point to an empty string.

lpszDirectory

A pointer to a string that specifies the current working directory for the program. If this parameter is NULL or points to an empty string, the server will use the current working directory of the client that issues the SITE EXEC command.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **RegisterProgram** method registers an executable program for use with the SITE EXEC command. Because this can present a significant security risk to the server, clients are not given permission to use this command by default. A client must be explicitly granted permission to use SITE EXEC by including FTP_ACCESS_EXECUTE as one of the permissions when authenticating the client session with the **AuthenticateClient** method or creating a virtual user using the **AddVirtualUser** method.

To give the server complete control over what programs can be executed using SITE EXEC, the program must be registered with the server and referenced by an alias specified by the *lpszCommandName* parameter. The maximum length of a program name is 31 characters and it must be at least 3 characters in length. The name must only consist of alphanumeric characters and the first character of the program name cannot be numeric. The program name is not case-sensitive, however convention is to use upper-case characters. If a program name is specified that already has been registered, it will be updated with the new information provided by this method.

The ***lpzProgramFile*** string specifies file name of the program that will be executed. You should not install any executable programs in the server root directory or its subdirectories. A client should never have the ability to directly access the executable file itself. It is permitted to have multiple command names that reference the same executable file. The only requirement is that the command names be unique. The program name may contain environment variables surrounded by % symbols. For example, %ProgramFiles% would be expanded to the **C:\Program Files** folder.

It is important to note that the program specified by ***lpzProgramFile*** must be an executable file, not a script or batch file. If the program name does not contain a directory path, then the standard Windows pathing rules will be used when searching for an executable file that matches the given name. It is recommended that you always provide a full path to the executable file.

The ***lpzParameters*** string is used to define optional command line parameters that will be included with the command. This string can contain placeholders that are replaced by additional parameters specified by the client when it sends the SITE EXEC command. First replacement parameter is %1, the second is %2 and so on.

The executable program that is registered using this method must be a console application that writes to standard output. Programs that write directly to a console, or programs written to use a Windows user interface are not supported and will yield unpredictable results. In most cases, those programs that do not use standard input and output will be forcibly terminated by the server. If the program attempts to read from standard input, it will immediately encounter an end-of-file condition. Programs executed by the SITE EXEC command have no input; it is similar to a program that has its input redirected from the NUL: device. If the program must process a file on the server, the local file name should be passed as a command line parameter.

The output from the program will be redirected back to the client control channel. The output should be textual, with each line of text terminated by a carriage return and linefeed (CRLF). Programs that write binary data to standard output, particular data with embedded nulls, will yield unpredictable results and are not supported. To ensure that the program output conforms to the protocol standard, any non-printable characters will be replaced with a space and each line of output will be prefixed by a single space. The server application can obtain a copy of the output from the last command by calling the **GetProgramOutput** method.

If the server is running on a system with User Account Control (UAC) enabled and does not have elevated privileges, do not register a program that requires elevated privileges or has a manifest that specifies the requestedExecutionLevel as requiring administrative privileges.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetProgramExitCode](#), [GetProgramName](#), [GetProgramOutput](#)

CFtpServer::RenameServerLogFile Method

```
BOOL RenameServerLogFile(  
    LPCTSTR lpszFileName  
);
```

Rename or delete the current log file being updated by the server.

Parameters

lpszFileName

A pointer to a string that specifies the file name the current log file should be renamed to. If this parameter is NULL or an empty string, the current log file will be deleted.

Return Value

If the method succeeds, the return value is non-zero. If logging is not currently enabled for the server, this method will return zero.

Remarks

The **RenameServerLogFile** method is used to rename or delete the current log file. Note that this does not change the current log file name or disable logging by the server. It only changes the file name of the current log file, or removes the log file if the *lpszFileName* parameter is NULL. This can be useful if you want your server to perform log file rotation, archiving the current log file. By renaming the current log file, the server will automatically create a new log file with original file name.

This method must be used to rename or delete the current log file while logging is active because the server holds an open handle on the file. The application should not use the **GetLogFile** method to obtain the log file name and then use the **MoveFileEx** or **DeleteFile** Windows API functions with that file.

To disable logging, use the **SetLogFile** method and specify the logging format as FTP_LOGFILE_NONE.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLogFile](#), [SetLogFile](#)

CFtpServer::Restart Method

BOOL Restart();

Restart the server, terminating all active client sessions.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Restart** method will restart the specified server, terminating all active client sessions. If the method is unable to restart the server for any reason, the server thread is terminated. The server retains all of the configuration parameters from the previous instance, however the statistical information (such as the number of clients, files transferred, etc.) will be reset.

If an application calls this method from within an event handler, the active client session (the client for which the event handler was invoked) may not get a disconnect notification. It is recommended that this method only be called by the same thread that created the server using the **Start** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

CFtpServer::Resume Method

BOOL Resume();

Resume accepting client connections.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Resume** method instructs the server to resume accepting new client connections after the **Suspend** method has been called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[Restart](#), [Start](#), [Stop](#), [Suspend](#), [Throttle](#)

CFtpServer::SendResponse Method

```
BOOL SendResponse(  
    UINT nClientId,  
    UINT nResultCode,  
    LPCTSTR lpszMessage  
);
```

Send a result code and message to the client in response to a command.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nResultCode

An unsigned integer value which specifies the result code.

lpszMessage

A pointer to a string which specifies a message to be sent to the client. If this parameter is NULL or points to an empty string, a default message associated with the result code will be used.

Return Value

If the result code and message text was sent to the client, the return value is non-zero. If the client ID does not specify a valid client session, or the result code is invalid, this method will return zero.

Remarks

The **SendResponse** method is used to respond to a command issued by the client. Command responses are normally handled by the server as a normal part of processing a command and this method is only used if the application has implemented custom commands or wishes to modify the standard responses sent by the server. The message may be a maximum of 2048 characters and may include embedded carriage-return and linefeed characters. If no message is specified, then a default message will be sent based on the result code.

Result codes must be three digits (in the range of 100 through 999) and although this method will support the use of non-standard result codes, it is recommended that the client application use the standard codes defined in RFC 959 whenever possible. The use of non-standard result codes may cause problems with FTP clients that expect specific result codes in response to a particular command. For more information, refer to the **GetCommandResult** method.

This method should only be called once in response to a command sent by the client. If a result code has already been sent in response to a command and this method is called, it will fail and return a value of zero. This is necessary because sending multiple result codes in response to a single command may cause unpredictable behavior by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandResult](#)

CFtpServer::SetAddress Method

```
BOOL SetAddress(  
    LPCTSTR lpszAddress  
);
```

Change the IP address that the server will use with passive data connections.

Parameters

lpszAddress

A pointer to a string that specifies the IP address that the server should use for passive mode data transfers. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If either the server handle or the IP address is invalid the method will return a value of zero.

Remarks

The **SetAddress** method changes the IP address that the server will use when a client transfers a file using a passive mode data connection. In passive mode, the server will create a second passive (listening) socket that will accept an incoming connection from the client. The server sends the IP address and port number allocated for that socket to the client, and the client establishes the data connection to the server using that address. The IP address that the server sends to the client is normally the same as the IP address that the client used to establish the control connection, however if the server is located behind a router that performs Network Address Translation (NAT), the IP address reported to the client may not be usable.

This method enables your application to set the external IP address for the server to a specific value, rather than the server attempting to automatically discover its own external address. If you wish to set the external address for the server manually, call the **Start** method without the FTP_SERVER_EXTERNAL option and then call this method to set the external IP address to the desired value.

This method will not change the IP address the server is using to listen for client connections. The only way to change the listening IP address is to stop and restart the server using the new address. This method only changes the IP address that is reported to clients when a passive data connection is used. Incorrect use of this method can prevent the client from establishing a data connection to the server. The address must be in the same address family as the local address that the server was started with. For example, if the server was started using an IPv4 address, the IP address passed to this method cannot be an IPv6 address.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetAddress](#), [GetName](#)

CFtpServer::SetCertificate Method

```
BOOL SetCertificate(  
    DWORD dwProtocol,  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName,  
    LPCTSTR lpszPassword  
);  
  
BOOL SetCertificate(  
    LPCTSTR lpszCertName,  
    LPCTSTR lpszPassword  
);
```

Set the name of the certificate to be used with secure connections.

Parameters

dwProtocol

A bitmask of supported security protocols. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.

SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

lpszCertStore

A pointer to a string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The function will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the function will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the function will return an error indicating that the certificate could not be found.

lpszPassword

An optional pointer to a string which specifies the certificate owner's password. A value of NULL specifies that no password is required. This parameter is only required if the *lpszCertStore* parameter specifies a certificate file in PKCS #12 format that is password protected.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

An application only needs to call this method to support secure connections using TLS. When a certificate is specified, it must have a private key associated with it. Attempting to use a certificate which does not have a private key will result in an error during the startup process indicating that the server credentials are invalid.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user, or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *lpzCertStore* parameter should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. If a password was specified when the certificate was created, it must be provided in the *lpzPassword* parameter or the class will be unable to access the certificate.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetOptions](#), [SetOptions](#)

CFtpServer::SetClientAccess Method

```
BOOL SetClientAccess(  
    UINT nClientId,  
    DWORD dwUserAccess  
);
```

Change the access rights associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more user access rights. For a list of user access rights that can be granted to the client, see [User Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method can only be used with authenticated clients. If the client session has not been authenticated, the return value will be zero.

Remarks

The **SetClientAccess** method can change the access rights for an authenticated client session. This method can only be used after the **AuthenticateClient** method has been used to grant the initial set of access rights to the client. The **EnableClientAccess** method can be used to grant or revoke a specific permission for the client session.

The *dwUserAccess* parameter has a value of FTP_ACCESS_DEFAULT, then default permissions will be granted to the client session. A normal client cannot be changed to a restricted or anonymous client using this method. If the FTP_ACCESS_RESTRICTED or FTP_ACCESS_ANONYMOUS access flags are specified, this method will fail.

This method cannot be used to change the access rights for a restricted or anonymous user. Those rights are granted when the client session is authenticated and will persist until the client disconnects from the server. This restriction is designed to prevent the inadvertent granting of rights to an untrusted client that could compromise the security of the server.

Example

```
DWORD dwUserAccess = 0;  
  
// Allow the client to execute programs using SITE EXEC  
if (pFtpServer->GetClientAccess(nClientId, dwUserAccess))  
{  
    if (! (dwUserAccess & FTP_ACCESS_ANONYMOUS))  
        pFtpServer->SetClientAccess(nClientId, dwUserAccess | FTP_ACCESS_EXECUTE);  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[AuthenticateClient](#), [EnableClientAccess](#), [GetClientAccess](#)

CFtpServer::SetClientFileType Method

```
BOOL SetClientFileType(  
    UINT nClientId,  
    UINT nFileType  
);
```

Change the current file type used for transfers by the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nFileType

Specifies the type of file that will be uploaded or downloaded. This parameter determines whether subsequent file transfers require any data conversion and may be one of the following values.

Value	Description
FILE_TYPE_ASCII	The file is a text file using the ASCII character set. For those clients which use a different end-of-line character sequence, the text file has been converted to the local format which uses the carriage return (CR) and linefeed (LF) characters.
FILE_TYPE_IMAGE	The file is a binary file and no data conversion of any type has been performed on the file. This is the default file type for most data files and executable programs. If the client specified this file type when appending to a text file, the file will contain the end-of-line sequences used by its native operating system.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **SetClientFileType** method will change the default file type that is used for subsequent transfers by the client. If the file type is set to FILE_TYPE_ASCII then the server will automatically convert any end-of-line character sequences to match the format used by the local system. For example, if the client is connecting from a UNIX based system, the server will convert a single linefeed character to a carriage return (CR) and linefeed (LF) sequence. If the file type is set to FILE_TYPE_IMAGE, then no conversion is performed.

This method can be used to override the file type specified by filtering the TYPE command issued by the client. For example, it could be used to force file transfers to use a specific type based on the file extension, regardless of the type specified by the client. To determine the current file type set by the client, use the **GetClientFileType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[GetClientFileType](#)

CFtpServer::SetClientIdentity Method

```
BOOL SetClientIdentity(  
    UINT nClientId,  
    LPCTSTR lpszIdentity  
);
```

Change the identity of the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszIdentity

A pointer to a string that identifies the client. If this parameter is NULL or specifies an empty string, the current identity for the client is cleared. The maximum length of the identity string is 64 characters, including the terminating null character.

Return Value

If the method succeeds, the return value is non-zero. If the client ID is invalid, the method will return a value of zero.

Remarks

The **SetClientIdentity** method associates a string value with the client that can be used to identify the session. The identity string does not have any standard format and is used for informational purposes only. Typically it is used to identify the client application that was used to establish the connection. Changing the client identity has no effect on the operation of the server. To obtain the identity string currently associated with the client, use the **GetClientIdentity** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientIdentity](#), [GetIdentity](#), [SetIdentity](#)

CFtpServer::SetClientIdleTime Method

```
UINT SetClientIdleTime(  
    UINT nClientId,  
    UINT nTimeout  
);
```

Change the idle timeout period for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nTimeout

An unsigned integer value that specifies the number of seconds that the client may remain idle. If this value is zero, the default idle timeout period for the server will be used.

Return Value

If the method succeeds, the return value is the previous client idle timeout period in seconds. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **SetClientIdleTime** method will change the number of seconds that the client may remain idle before being automatically disconnected by the server. The minimum timeout period for a client is 60 seconds, the maximum is 7200 seconds (2 hours). The idle time of a client session is based on the last time a command was issued to the server or when a data transfer completed.

If the value INFINITE is specified as the timeout period, the client activity timer will be refreshed, extending the idle timeout period for the session. This is typically done inside an **OnTimeout** event handler to prevent the client from being disconnected due to inactivity.

To obtain the current idle timeout period for a client, along with the amount of time the client has been idle, use the **GetClientIdleTime** method.

This timeout period only affects authenticated clients. Unauthenticated clients use a different internal timer that limits the amount of time they can remain connected to the server and that value cannot be changed for individual client sessions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftsv11.lib

See Also

[GetClientIdleTime](#)

CFtpServer::SetCommandFile Method

```
BOOL SetCommandFile(  
    UINT nClientId,  
    LPCTSTR lpszFileName  
);
```

Change the name of the local file or directory that is the target of the current command.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the new file name. This parameter may be NULL to specify that the original file or directory name should be used.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **SetCommandFile** method is used by the application to change the target file or directory name for the current command from within the **OnCommand** event handler. This can be used to effectively redirect the client to use a different file than the one that was actually requested. For example, if the client issues the RETR command to download a file from the server, this method can be used to redirect the command to use a different file name. To obtain the full path to the file or directory that is the target of the current command, use the **GetCommandFile** method.

The *lpszFileName* parameter specifies the path to the new file or directory name. If the path is absolute, then it will be used as-is. If the path is relative, it will be relative to the current working directory for the client session. The full path to this file is not limited to the server root directory or its subdirectory, it can specify a file anywhere on the local system. If this parameter is a NULL pointer, or points to an empty string, then the server will revert to using the actual file or directory name specified by the command. This enables the application to effectively undo a previous call to this method to change the target file name.

Typically this method would be used to redirect a client to a file or directory that it may not normally have access to. Exercise caution when using this method to provide access to data that is stored outside of the server root directory. Incorrect use of this method could expose the server to security risks or cause unpredictable behavior by client applications.

This method should only be called within the context of the **OnCommand** event handler, and only for those commands that perform an action on a file or directory. If the current command does not target a file or directory, this method will return zero and the last error code will be set to ST_ERROR_INVALID_COMMAND. To obtain the name of the current command issued by the client, use the **GetCommandName** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#) [GetCommandLine](#), [GetCommandName](#)

CFtpServer::SetDirectory Method

```
BOOL SetDirectory(  
    LPCTSTR lpszDirectory  
);
```

Specify the local directory that will be used as the server root directory.

Parameters

lpszDirectory

A pointer to a string that specifies the root directory for the server. If this parameter is NULL or a zero-length string, the server will use the current working directory as the root directory.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero.

Remarks

The **SetDirectory** method specifies the path to the local directory that should be used as the root document directory for the server.

It is recommended that you always specify an absolute path for the server root directory. If the path includes environment variables surrounded by percent (%) symbols, they will be automatically expanded.

If you have configured the server to permit clients to upload files, you must ensure that your application has permission to create files in the directory that you specify. A recommended location for the server root directory would be a subdirectory of the %ALLUSERSPROFILE% directory. Using the environment variable ensures that your server will work correctly on different versions of Windows. If the root directory does not exist at the time that the server is started, it will be created.

You cannot change the server root directory after the server has started. To change the root directory, you must stop the server using the **Stop** method and then start another instance of the server with a configuration that specifies the new directory.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetDirectory](#)

CFtpServer::SetIdentity Method

```
BOOL SetIdentity(  
    LPCTSTR lpszIdentity  
);
```

Change the identity of the specified server.

Parameters

lpszIdentity

A pointer to a string that identifies the server. If this parameter is NULL or specifies an empty string, the current identity for the server is reset to a default value. The maximum length of the identity string is 64 characters, including the terminating null character.

Return Value

If the method succeeds, the return value is non-zero, otherwise it will return a value of zero.

Remarks

The **SetClientIdentity** method changes a string value used by the server to identify itself to clients. The identity string does not have any standard format and is used for informational purposes only. Typically it consists of the application name and a version number. Changing the server identity has no effect on the operation of the server. To obtain the identity string currently associated with the server, use the **GetIdentity** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientIdentity](#), [SetClientIdentity](#), [GetIdentity](#)

CFtpServer::SetLastError Method

```
VOID SetLastError(  
    DWORD dwError  
);
```

Set the last error code for the specified server session.

Parameters

dwError

An unsigned integer that specifies an error code.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each server session. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_SERVER or FTP_ERROR.

If the *dwError* parameter is specified with a value of zero, this effectively clears the error code for the last method that failed. Those methods which clear the last error code when they succeed are noted on their reference page.

Applications can retrieve the value saved by this method by calling the **GetLastError** method to determine the specific reason for failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftsv11.lib

See Also

[GetCommandResult](#), [GetLastError](#), [SendResponse](#)

CFtpServer::SetLogFile Method

```
BOOL SetLogFile(  
    UINT nLogFormat,  
    UINT nLogLevel,  
    LPCTSTR lpszFileName  
);
```

Change the current log format, level of detail and file name.

Parameters

nLogFormat

An integer value that specifies the format used when creating or updating the server log file. The following formats are supported:

Value	Description
FTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
FTP_LOGFILE_COMMON	This value specifies that the log file should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about file transfers.
FTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session.

nLogLevel

An integer value that specifies the level of detail that should be generated in the log file. The minimum value is 1 and the maximum value is 10. If this parameter is zero, it is the same as specifying a log file format of FTP_LOGFILE_NONE and will disable logging by the server.

lpszFileName

A pointer to a string that specifies the name of the log file that should be created or appended to. If the server was configured with logging enabled and this parameter is NULL or an empty string, the current log file name will not be changed. If the log file does not exist, it will be created. If it does exist, the contents of the log file will be appended to.

Return Value

If the method succeeds, the return value is non-zero. If one of the parameters are invalid, the method will return zero.

Remarks

The **SetLogFile** method can be used to change the current log file name, the format of the log file or the level of detail recorded in the log file. In some situations it may be desirable to delete the current log file contents when changing the format or ensure that a new log file is created. To do this, combine the *nLogFormat* parameter with the constant FTP_LOGFILE_DELETE.

The higher the value of the *nLogLevel* parameter, the greater the level of detail that is recorded by the server. A log level of 1 instructs the server to only record file transfers, while a level of 10 instructs the server to record all commands processed by the server. Because a higher level of logging detail can negatively impact the performance of the server, it is recommended that you do not exceed a level of

5 for most applications. A log level of 10 should only be used for debugging purposes.

Example

```
UINT nLogFormat = FTP_LOGFILE_NONE;
UINT nLogLevel = 0;
UINT nNewLevel = 5;
BOOL bChanged = FALSE;

// Change the level of detail for the current log file if logging
// has been enabled and the current level is a lower value

if (pFtpServer->GetLogFile(&nLogFormat, &nLogLevel, NULL, 0))
{
    if (nLogFormat != FTP_LOGFILE_NONE && nLogLevel < nNewLevel)
        bChanged = pFtpServer->SetLogFile(nLogFormat, nNewLevel, NULL);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetLogFile](#), [RenameServerLogFile](#)

CFtpServer::SetName Method

```
BOOL SetName(  
    UINT nClientId,  
    LPCTSTR lpszHostName  
);
```

Change the host name assigned to the specified server or client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszHostName

A pointer to a string that specifies the new host name assigned to the server or client session. If this value is NULL or points to an empty string, the current host name will be changed to use the default host name.

Return Value

If the method succeeds, the return value is non-zero. If the client ID is invalid, or the buffer is not large enough to store the complete hostname, the method will return a value of zero.

Remarks

This method will change the host name assigned to the specified client session. If the *nClientId* parameter has a value of zero, the method will change default host name that was assigned to the server as part of the server configuration. If the *nClientId* parameter specifies a valid client session and the *lpszHostName* parameter is NULL, the host name associated with the client session will be changed to the current host name assigned to the server.

When a client connects to the server, it can specify the host name that it used to establish the connection by sending the HOST command. This is typically used with virtual hosting, where one server may accept client connections for multiple domains. The **GetName** method will return the host name specified by the client, and **SetName** can be used by the application to either explicitly assign a different host name to the client session, or override the host name provided by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetAddress](#), [GetName](#)

CFtpServer::SetOptions Method

```
BOOL SetOptions(  
    DWORD dwOptions  
);
```

Sets the default options for this instance of the server.

Parameters

dwOptions

An unsigned integer which specifies one or more options. For a list of available options, see [Server Option Constants](#).

Return Value

If the method is successful, it will return a non-zero value, otherwise it will return a value of zero.

Remarks

The **SetOptions** method changes the default options for the current instance of the server. This method cannot be used to change the options for an active instance of the server. If the server is active, it must be stopped before calling this method. To get the current options, use the **GetOptions** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[GetOptions](#)

CFtpServer::SetPriority Method

```
INT SetPriority(  
    INT nPriority  
);
```

Change the priority assigned to the specified server.

Parameters

nPriority

An integer value which specifies the new priority for the server. It may be one of the following values:

Value	Description
FTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the server. It is typically used with lightweight services running in the background that are designed for few client connections. The server thread will be assigned a lower scheduling priority and will be frequently forced to yield execution to other threads.
FTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the server and meters the processor utilization for the server thread. The server thread will be assigned a lower scheduling priority and will occasionally be forced to yield execution to other threads.
FTP_PRIORITY_NORMAL	The default priority which balances resource and processor utilization. This is the priority that is initially assigned to the server when it is started, and it is recommended that most applications use this priority.
FTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the server and the thread will be given higher scheduling priority. It is not recommended that this priority be used on a system with a single processor.
FTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization. The server thread will be given higher scheduling priority and will be more responsive to client connection requests. It is not recommended that this priority be used on a system with a single processor.

Return Value

If the method succeeds, the return value is the previous priority assigned to the server. If the method fails, the return value is FTP_PRIORITY_INVALID. To get extended error information, call the **GetLastError** method.

Remarks

The **SetPriority** method can be used to change the current priority assigned to the specified server. Client connections that are accepted after this method is called will inherit the new priority as their

default priority. Previously existing client connections will not be affected by this method.

Higher priority values increase the thread priority and processor utilization for each client session. You should only change the server priority if you understand the impact it will have on the system and have thoroughly tested your application. Configuring the server to run with a higher priority can have a negative effect on the performance of other programs running on the system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[GetPriority](#), [Start](#)

CFtpServer::SetStackSize Method

```
BOOL SetStackSize(  
    DWORD dwStackSize  
);
```

Change the initial size of the stack allocated for threads created by the server.

Parameters

dwStackSize

The amount of memory that will be committed to the stack for each thread created by the server. If this value is zero, a default stack size will be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **SetStackSize** method changes the initial amount of memory that is committed to the stack for each thread created by the server. By default, the stack size for each thread is set to 256K for 32-bit processes and 512K for 64-bit processes. Increasing or decreasing the stack size will only affect new threads that are created by the server, it will not affect those threads that have already been created to manage active client sessions. It is recommended that most applications use the default stack size.

You should not change this value unless you understand the impact that it will have on your system and have thoroughly tested your application. Increasing the initial commit size of the stack will remove pages from the total system commit limit, and every page of memory that is reserved for stack cannot be used for any other purpose.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[GetStackSize](#), [Start](#)

CFtpServer::SetUuid Method

```
BOOL SetUuid(  
    LPCTSTR lpszHostUuid  
);
```

Assign a UUID to the current instance of the server.

Parameters

lpszHostUuid

A pointer to a string that specifies the server UUID, terminated with a null character. This value can be used when storing information about the server, and should be generated using a utility such as **uuidgen** which is included with Visual Studio. This parameter may be NULL or point to an empty string, in which case a temporary UUID will be randomly generated for the server.

Return Value

If the method succeeds, the return value is non-zero, otherwise the method return a value of zero.

Remarks

The **SetUuid** method assigns a Universally Unique Identifier (UUID) to the server. The UUID may either be generated by the application and assigned as part of the server configuration, or an ephemeral UUID may be automatically generated when the server is started. This method cannot be used to change the UUID after the server has been started. To determine the UUID assigned to an active server instance, use the **GetUuid** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetUuid](#)

CFtpServer::Start Method

```
BOOL Start(  
    LPCTSTR lpszLocalHost,  
    UINT nLocalPort,  
    DWORD dwOptions  
);  
  
BOOL Start(  
    LPCTSTR lpszLocalHost,  
    UINT nLocalPort  
);  
  
BOOL Start(  
    UINT nLocalPort  
);
```

The **Start** method begins listening for client connections on the specified local address and port number. The server is started in its own thread and manages the client sessions independently of the calling thread. All interaction with the server and its client sessions takes place inside the class event handlers.

Parameters

lpszLocalHost

A pointer to a string which specifies the local hostname or IP address address that the server should be bound to. If this parameter is omitted or specifies a NULL pointer an appropriate address will automatically be used. If a specific address is used, the server will only accept client connections on the network interface that is bound to that address.

nLocalPort

The port number the server should use to listen for client connections. If a value of zero is specified, the server will use the standard port number 21 to listen for connections, or port 990 if the server is configured to use implicit TLS. The port number used by the application must be unique and multiple instances of a server cannot use the same port number. It is recommended that a port number greater than 5000 be used for private, application-specific implementations.

dwOptions

An unsigned integer value that specifies one or more options to be used when creating an instance of the server. For a list of the available options, see [Server Option Constants](#). If this parameter is omitted, the default options for the server instance will be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

In most cases, the *lpszLocalHost* parameter should be omitted or a NULL pointer. On a multihomed system, this will enable the server to accept connections on any appropriately configured network adapter. Specifying a hostname or IP address will limit client connections to that particular address. Note that the hostname or address must be one that is assigned to the local system, otherwise an error will occur.

If an IPv6 address is specified as the local address, the system must have an IPv6 stack installed and configured, otherwise the method will fail.

To listen for connections on any suitable IPv4 interface, specify the special dotted-quad address "0.0.0.0". You can accept connections from clients using either IPv4 or IPv6 on the same socket by specifying the special IPv6 address "::0", however this is only supported on Windows 7 and Windows Server 2008 R2 or later platforms. If no local address is specified, then the server will only listen for connections from clients using IPv4. This behavior is by design for backwards compatibility with systems that do not have an IPv6 TCP/IP stack installed.

The handle returned by this method references the listening socket that was created when the server was started. The service is managed in another thread, and all interaction with the server and active client connections are performed inside the event handlers. To disconnect all active connections, close the listening socket and terminate the server thread, call the **Stop** method.

The host UUID that is defined as part of the server configuration should be generated using the **uuidgen** utility that is included with the Windows SDK. You should not use the UUID that is provided in the example code, it is for demonstration purposes only. If no host UUID is specified in the server configuration, an ephemeral UUID will be generated automatically when the server is started.

Example

```
CFtpServer *pFtpServer = new CFtpServer();

// Initialize the server configuration
pFtpServer->SetName(_T("server.company.com"));
pFtpServer->SetUuid(_T("10000000-1000-1000-1000-100000000000"));
pFtpServer->SetDirectory(_T("%ProgramData%\\MyProgram\\Server"));
pFtpServer->SetLogFile(FTP_LOGFILE_EXTENDED, 5,
    _T("%ProgramData%\\MyProgram\\Server.log"));
pFtpServer->SetOptions(FTP_SERVER_LOCALUSER | FTP_SERVER_UNIXMODE);

// Start the server
pFtpServer->Start(FTP_PORT_DEFAULT);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnumClients](#), [Restart](#), [Stop](#)

CFtpServer::Stop Method

BOOL Stop();

Stop the server, terminating all active client sessions and releasing the resources that were allocated for the server.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return a value of zero.

Remarks

The **Stop** method instructs the server to stop accepting client connections, disconnects all active client connections and terminates the thread that is managing the server session. The handle is no longer valid after the server has been stopped and should no longer be used. Note that it is possible that the actual handle value may be re-used at a later point when a new server is started. An application should always consider the server handle to be opaque and never depend on it being a specific value.

If an application calls this method from within an event handler, the active client session (the client for which the event handler was invoked) may not get a disconnect notification. It is recommended that this method only be called by the same thread that created the server using the **Start** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[Restart](#), [Start](#)

CFtpServer::Suspend Method

BOOL Suspend();

Suspend the server and reject new client connections.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Suspend** method instructs the server to suspend accepting new client connections. Any incoming client connections will be rejected with an error message indicating that the server is currently unavailable. To resume accepting client connections, call the **Resume** method. Suspending the server will have no effect on clients that have already established a connection with the server.

It is recommended that you only suspend a server if absolutely necessary, and only for brief periods of time. If you want to limit the number of active client connections or control the connection rate for clients, use the **Throttle** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[Restart](#), [Resume](#), [Start](#), [Stop](#), [Throttle](#)

CFtpServer::Throttle Method

```
BOOL Throttle(  
    UINT nMaxClients,  
    UINT nMaxClientsPerAddress,  
    UINT nMaxGuests,  
    DWORD dwConnectionRate  
);
```

The **Throttle** method limits the number of active client connections, connections per address and connection rate.

Parameters

nMaxClients

A value which specifies the maximum number of clients that may connect to the server. A value of zero specifies that there is no fixed limit to the number of client connections. A value of -1 specifies that the maximum number of clients should not be changed.

nMaxClientsPerAddress

A value which specifies the maximum number of clients that may connect to the server from the same IP address. A value of zero specifies that there is no fixed limit to the number of client connections per address. By default, there is a limit of four client connections per address. A value of -1 specifies that the maximum number of clients should not be changed.

nMaxGuests

An integer value which specifies the maximum number of guest users that may login to the server. A value of zero disables guest logins and requires that all clients authenticate with a valid username and password. A value of -1 specifies that the maximum number of guest users should not be changed.

dwConnectionRate

A value which specifies a restriction on the rate of client connections, limiting the number of connections that will be accepted within that period of time. A value of zero specifies that there is no restriction on the rate of client connections. The higher this value, the fewer the number of connections that will be accepted within a specific period of time. By default, there is no limit on the client connection rate. A value of -1 specifies that the connection rate should not be changed.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Throttle** method is used to limit the number of connections and the connection rate to minimize the potential impact of a large number of client connections over a short period of time. This can be used to protect the server from a client application that is malfunctioning or a deliberate denial-of-service attack in which the attacker attempts to flood the server with connection attempts.

If the maximum number of client connections or maximum number of connections per address is exceeded, the server will reject subsequent connection attempts until the number of active client sessions drops below the specified threshold. Note that adjusting these values lower than the current connection limits will not affect clients that have already connected to the server. For example, if the **Start** method is called with the maximum number of clients set to 100, and then **Throttle** is called lowering that value to 75, no existing client connections will be affected by the change. However, the

server will not accept any new connections until the number of active clients drops below 75.

Increasing the connection rate value will force the server to slow down the rate at which it will accept incoming client connection requests. For example, setting this parameter to a value of 1000 would limit the server to accepting one client connection every second, while a value of 250 would allow the server to accept four client connections per second. Note that significantly increasing the amount of time the server must wait to accept client connections can exceed the connection backlog queue, resulting in client connections being rejected.

It is recommended that you always specify conservative connection limits for your server application based on expected usage. Allowing an unlimited number of client connections can potentially expose the system to denial-of-service attacks and should never be done for servers that are accessible over the Internet.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

[Restart](#), [Resume](#), [Start](#), [Suspend](#)

CFtpServer Event Handlers

Method	Description
OnAuthenticate	The client requested authentication
OnCommand	The client issued a command to the server
OnConnect	The client established a connection to the server
OnDisconnect	The client has disconnected from the server
OnDownload	The client has downloaded a file from the server
OnError	The server encountered an error while handling a client request
OnExecute	The client has executed an external program on the server
OnLogin	The client has successfully authenticated the session
OnLogout	The client has logged out or reinitialized the session
OnResult	The command issued by the client has been processed by the server
OnTimeout	The client has exceeded the maximum allowed idle time
OnUpload	The client has uploaded a file to the server

CFtpServer::OnAuthenticate Method

```
virtual void OnAuthenticate(  
    UINT nClientId,  
    LPCTSTR lpszHostName,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword  
);
```

A virtual method that is invoked after the client has requested authentication.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszHostName

A pointer to a string that specifies the host name that the client used to establish the connection.

lpszUserName

A pointer to a string that specifies the user name provided by the client.

lpszPassword

A pointer to a string that specifies the cleartext user password provided by the client.

Return Value

None.

Remarks

The **OnAuthenticate** event handler is invoked when the client has requested authentication by sending the USER and PASS command to the server. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

The event handler can call the **AuthenticateClient** method to authenticate the client session. To reject an authentication attempt because of an invalid user name or password, the handler should call the **SendResponse** method and specify a result code of 430.

If the client session is not authenticated, the server will perform its default authentication process. If the FTP_SERVER_ANONYMOUS configuration option has been specified, and the client has logged in as an anonymous user, the session will be authenticated as a restricted user. If the FTP_SERVER_LOCALUSER configuration option has been specified, the user name and password is checked against the local user database. If the credentials are valid, the session will be authenticated as a regular user. If neither the FTP_SERVER_ANONYMOUS or FTP_SERVER_LOCALUSER options were specified, the default action is to reject all authentication attempts.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[SendResponse](#), [OnLogin](#), [OnLogout](#)

CFtpServer::OnCommand Method

```
virtual void OnCommand(  
    UINT nClientId,  
    LPCTSTR lpszCommand  
);
```

A virtual method that is invoked after the client has sent a command to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string that specifies the command issued by the client. The command name will always be capitalized. For a complete list of commands supported by the server, see [Server Commands](#).

Return Value

None.

Remarks

The **OnCommand** event handler is invoked after the client has sent a command to the server, but before the command has been processed. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

This event handler is invoked for all commands issued by the client, including invalid or disabled commands. If the event handler processes the command, it must call the **SendResponse** method to send a success or error response back to the client. If this is not done, the server will perform the default processing for the command.

Although this event handler will provide the command name, the full command line can be obtained by using the **GetCommandLine** method. Individual command parameters can be obtained by using the **GetCommandParam** and **GetCommandParamCount** methods.

It is not necessary to use this event handler to disable a command. The **EnableCommand** method can be used to enable or disable specific commands, and the **IsCommandEnabled** method can be used to determine if a command is enabled.

If this event handler is used to implement a custom command, it is recommended that you use the **IsClientAuthenticated** method to determine whether or not the client session has been authenticated. Unless there is a specific need for the custom command to be used before a client has logged in, the application should not take any action and send a 530 result code back to the client indicating authentication is required.

Example

```
VOID CMyFtpServer::OnCommand(UINT nClientId, LPCTSTR lpszCommand)  
{  
    // Implement a custom command named TIME that will return the local time  
    if (lstrcmp(lpszCommand, _T("TIME")) == 0)  
    {  
        // The command should not have any parameters  
        if (GetCommandParamCount(nClientId) > 0)  
        {  
            SendResponse(nClientId, FTP_REPLY_BADARG);  
        }  
    }  
}
```

```

        return;
    }

    if (IsClientAuthenticated(nClientId))
    {
        CString strTime = CTime::GetCurrentTime().Format(_T("%Y-%m-%d
%H:%M:%S"));
        SendResponse(nClientId, FTP_REPLY_CMDOK, strTime);
    }
    else
    {
        // The client has not logged in, return an error
        SendResponse(nClientId, FTP_REPLY_NOLOGIN);
    }
}
}

```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisconnectClient](#), [EnableCommand](#), [IsCommandEnabled](#), [OnDisconnect](#), [SendResponse](#)

CFtpServer::OnConnect Method

```
virtual void OnConnect(  
    UINT nClientId,  
    LPCTSTR lpszAddress  
);
```

A virtual method that is invoked after the client has connected to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszAddress

A pointer to a string that specifies the IP address of the client. This address may either be in IPv4 or IPv6 format, depending on how the server was configured and the address the client used to establish the connection.

Return Value

None.

Remarks

The **OnConnect** event handler is invoked after the client has connected to the server. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

This event only occurs after the server has checked the active client limits and the TLS handshake has been performed, if security has been enabled. If the server has been suspended, or the limit on the maximum number of client sessions has been exceeded, the server will terminate the client session prior to this event handler being invoked.

If this event handler is not implemented, the server will perform the default action of accepting the connection and sending a standard greeting to the client. If you want your application to send a custom greeting to the client when it connects, call the **SendResponse** method, specifying a result code of 220 and a message of your choice.

To reject a connection, call the **SendResponse** method to send an error response to the client. Typically the result code value would be 421 to indicate that the server will not accept the connection. Next, call the **DisconnectClient** method to terminate the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisconnectClient](#), [OnDisconnect](#), [SendResponse](#)

CFtpServer::OnDisconnect Method

```
virtual void OnDisconnect(  
    UINT nClientId  
);
```

A virtual method that is invoked immediately before the client is disconnected from the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

None.

Remarks

The **OnDisconnect** event handler is invoked immediately before the client is disconnected from the server. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

See Also

[OnConnect](#), [OnLogout](#)

CFtpServer::OnDownload Method

```
virtual void OnDownload(  
    UINT nClientId,  
    LPCTSTR lpszFileName,  
    DWORD dwTimeElapsed,  
    ULARGE_INTEGER uiBytesCopied  
);
```

A virtual method that is invoked after the client has successfully downloaded a file from the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the local path name of the file that was downloaded from the server. The path will always include the disk volume or share name, and the path delimiter will always be the backslash character.

dwTimeElapsed

An unsigned integer value that specifies the number of milliseconds that it took to complete the file transfer.

uiBytesCopied

An unsigned 64-bit integer value that specifies the number of bytes of data that was downloaded by the client.

Return Value

None.

Remarks

The **OnDownload** event handler is invoked after the client has successfully downloaded a file from the server using the RETR command. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

The ULARGE_INTEGER structure is actually a union that is used to represent a 64-bit value. If the compiler has built-in support for 64-bit integers, use the **QuadPart** member to access the 64-bit integer value. Otherwise, use the **LowPart** and **HighPart** members to access the value.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[OnCommand](#), [OnUpload](#)

CFtpServer::OnError Method

```
virtual void OnConnect(  
    UINT nClientId,  
    UINT nEventId,  
    DWORD dwError  
);
```

A virtual method that is invoked when the server encounters an error while handling a client request.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nEventId

An unsigned integer which identifies the client event that was being processed when the error occurred. For a list of event identifiers, see [Server Event Constants](#).

dwError

An unsigned integer value that specifies the error code.

Return Value

None.

Remarks

The **OnError** event handler is invoked whenever an error occurs while an event is being processed by the server. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

It is important to note that this event is not raised for every error that occurs. The event only occurs when another event is being processed and an unhandled error occurs that must be reported back to the server application. The following are some common situations in which this event handler may be invoked:

- A network error occurs when the client connection is being accepted by the server. This could be the result of an aborted connection or some other lower-level failure reported by the networking subsystem on the server.
- The server is configured to use implicit TLS but cannot obtain the security credentials required to create the security context for the session. Usually this indicates that the server certificate cannot be found, or the certificate does not have a private key associated with it. It could also indicate a general problem with the cryptographic subsystem where the client and server could not successfully negotiate a cipher suite.
- A network error occurs when attempting to process a command issued by the client. This usually indicates that the connection to the client has been aborted, either because the client is not acknowledging the data that has been exchanged with the server, or the client has terminated abnormally. This event will not occur if the client terminates the connection normally.

In most situations where this event handler is invoked, the error is not recoverable and the only action that can be taken is to terminate the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

[OnConnect](#), [OnCommand](#)

CFtpServer::OnExecute Method

```
virtual void OnExecute(  
    UINT nClientId,  
    LPCTSTR lpszProgram,  
    DWORD dwExitCode  
);
```

A virtual method that is invoked after the client has successfully executed an external program on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszProgram

A pointer to a string that specifies the name of the program that was executed. This is the registered program name, and not a full path to the executable and its command arguments.

dwExitCode

An unsigned integer that specifies the exit code that was returned by the program.

Return Value

None.

Remarks

The **OnExecute** event handler is invoked after the client has successfully executed an external program using the SITE EXEC command. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

This event will only be generated if the client has the FTP_ACCESS_EXECUTE permission. Clients are not granted this permission by default, and must be explicitly permitted to execute external programs. If the client does have this permission, it can only execute specific programs that have been registered by the server application using the **RegisterProgram** method.

The **GetProgramOutput** method can be used to obtain the unfiltered output from the external command, while the **GetProgramText** method will return filtered output from the program that contains only printable text characters.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::OnLogin Method

```
virtual void OnLogin(  
    UINT nClientId,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszDirectory,  
    LPCTSTR dwUserAccess  
);
```

A virtual method that is invoked after the client has successfully authenticated the session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszUserName

A pointer to a string that specifies the user name.

lpszDirectory

A pointer to a string that specifies the full path to the home directory for the client. The path will always include the disk volume or share name, and the path delimiter will always be the backslash character.

dwUserAccess

An unsigned integer which specifies one or more access rights for the client session. For a list of user access rights that can be granted to the client, see [User Access Constants](#).

Return Value

None.

Remarks

The **OnLogin** event handler is invoked after the client has successfully authenticated itself using the USER and PASS commands. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

To convert the home directory path to a virtual path name that is relative to the server root directory, use the **GetClientVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddVirtualUser](#), [AuthenticateClient](#), [OnAuthenticate](#), [OnLogout](#)

CFtpServer::OnLogout Method

```
virtual void OnLogout(  
    UINT nClientId,  
    LPCTSTR lpszUserName  
);
```

A virtual method that is invoked after the client has logged out or reinitialized the session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszUserName

A pointer to a string that specifies the user name.

Return Value

None.

Remarks

The **OnLogout** event handler is invoked after the client has successfully logged out using the QUIT command or reinitialized the session using the REIN command. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

The application should not depend on this event handler always being invoked when a client is disconnected from the server. This event only occurs when the client sends the QUIT or REIN commands and will not be invoked if the client connection is aborted or disconnected for some other reason, such as exceeding the idle timeout period. If the application needs to update data structures or perform some cleanup when a client disconnects, that should be done in the **OnDisconnect** event handler.

The application should not call the **DisconnectClient** method in the handler for this event because the client is either in the process of disconnecting or expects that it can submit new credentials to the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CFtpServer::OnResult Method

```
virtual void OnResult(  
    UINT nClientId,  
    LPCTSTR lpszCommand,  
    UINT nResultCode  
);
```

A virtual method that is invoked after the server has processed a command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string that specifies the command that was issued by the client. This value contains only the command and not the additional parameters that may have been specified.

nResultCode

An integer value that specifies the result code that was sent to the client.

Return Value

None.

Remarks

The **OnResult** event handler is invoked after the server has processed a command issued by the client. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

To obtain the complete command line, use the **GetCommandLine** method, or use the **GetCommandParam** method to get the value of specific command parameters. If the application requires the text message that was sent to the client along with the result code, use the **GetCommandResult** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandLine](#), [GetCommandParam](#), [GetCommandResult](#), [OnCommand](#)

CFtpServer::OnTimeout Method

```
virtual void OnTimeout(  
    UINT nClientId,  
    UINT nIdleTime,  
    UINT nElapsed  
);
```

A virtual method that is invoked after the client has exceeded the maximum allowed idle time.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nIdleTime

An unsigned integer value that specifies the current idle timeout period for the client in seconds.

nElapsed

An unsigned integer value that specifies the number of seconds that the client has been idle.

Return Value

None.

Remarks

The **OnTimeout** event handler is invoked after the client has exceeded the maximum allowed idle time. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

This event handler will be invoked prior to the client being disconnected from the server. This event will never occur during a file transfer or directory listing. The **SetClientIdleTime** method can be used to change or refresh the idle timeout period for the session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csftsv11.lib

See Also

[GetClientIdleTime](#), [OnCommand](#), [OnResult](#), [SetClientIdleTime](#)

CFtpServer::OnUpload Method

```
virtual void OnUpload(  
    UINT nClientId,  
    LPCTSTR lpszFileName,  
    DWORD dwTimeElapsed,  
    ULARGE_INTEGER uiBytesCopied  
);
```

A virtual method that is invoked after the client has successfully uploaded a file to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the local path name of the file that was uploaded to the server. The path will always include the disk volume or share name, and the path delimiter will always be the backslash character.

dwTimeElapsed

An unsigned integer value that specifies the number of milliseconds that it took to complete the file transfer.

uiBytesCopied

An unsigned 64-bit integer value that specifies the number of bytes of data that was uploaded by the client.

Return Value

None.

Remarks

The **OnUpload** event handler is invoked after the client has successfully uploaded a file to the server using the APPE, STOR or STOU command. To implement an event handler, the application should create a class derived from the **CFtpServer** class, and then override this method.

The ULARGE_INTEGER structure is actually a union that is used to represent a 64-bit value. If the compiler has built-in support for 64-bit integers, use the **QuadPart** member to access the 64-bit integer value. Otherwise, use the **LowPart** and **HighPart** members to access the value.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csftsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[OnCommand](#), [OnDownload](#)

CFtpServer Data Structures

- [FTPCLIENTCREDENTIALS](#)
- [FTPSERVERTRANSFER](#)

FTPCLIENTCREDENTIALS

The **FTPCLIENTCREDENTIALS** structure defines the credentials used to authenticate a specific user.

```
typedef struct _FTPCLIENTCREDENTIALS
{
    DWORD dwSize;
    DWORD dwFlags;
    TCHAR szHostName[FTP_MAXHOSTNAME];
    TCHAR szUserName[FTP_MAXUSERNAME];
    TCHAR szPassword[FTP_MAXPASSWORD];
} FTPCLIENTCREDENTIALS, *LPFTPCLIENTCREDENTIALS;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwFlags

An unsigned integer value reserved for future use. This member will always be initialized to a value of zero.

szHostName

A pointer to a string that specifies the server host name.

szUserName

A pointer to a string that specifies the user name.

szPassword

A pointer to a string that specifies the user password.

Remarks

When an instance of this structure is passed to the **GetClientCredentials** method, this member must be initialized to the size of the structure and all other members must be initialized with a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientCredentials](#)

FTPSEVERTRANSFER

The **FTPSEVERTRANSFER** structure provides information about the last file transfer performed by a client.

```
typedef struct _FTPSEVERTRANSFER
{
    DWORD          dwSize;
    DWORD          dwReserved;
    DWORD          dwFileAccess;
    DWORD          dwTimeElapsed;
    ULARGE_INTEGER uiBytesCopied;
    TCHAR          szFileName[MAX_PATH];
} FTPSEVERTRANSFER, *LPFTPSEVERTRANSFER;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwReserved

An unsigned integer value that is reserved for future use. This value will always be zero.

dwFileAccess

An unsigned integer value that specifies the how the local file was accessed. It can be one of the following values:

Value	Description
FTP_FILE_READ	The file was opened for reading. This mode indicates that the client issued the RETR command to download the contents of a file from the server to the client system. The <i>szFileName</i> member specifies the name of the local file on the server that was downloaded by the client.
FTP_FILE_WRITE	The file was opened for writing. This mode indicates that the client issued the STOR or STOU command to upload the contents of a file from the client system to server. The <i>szFileName</i> member specifies the name of the local file on the server that was created by the client. If a file already existed with the name name, it was replaced.
FTP_FILE_APPEND	The file was opened for writing. This mode indicates the client issued the APPE command to upload the contents of a file from the client system and append the data to a file on the server. If the file did not exist, then it was created. The <i>szFileName</i> member specifies the name of the local file that was appended to or created by the client.

dwTimeElapsed

The amount of time that it took for the file transfer to complete in milliseconds. This value is limited to the resolution of the system timer, which is typically in the range of 10 to 16 milliseconds. This value may be zero if the transfer occurred over a local network or on the same host using a loopback address.

uiBytesCopied

A 64-bit integer value that specifies the total number of bytes copied during the file transfer. This value is represented by a ULARGE_INTEGER union which provides support for those programming languages that do not have intrinsic support for 64-bit integers. For more information, refer to the

Windows SDK documentation. The application should not make the assumption that this is the actual size of the file. If the client specified a restart offset using the REST command, this value would only represent the number of bytes transferred from that byte offset, not the total file size.

szFileName

A pointer to a string value that will contain the full path to the local file that was transferred. The ***dwFileAccess*** member determines whether the file name represents a file that was downloaded by the client, or uploaded from the client and stored on the server.

Remarks

When an instance of this structure is passed to the **GetTransferInfo** method, the ***dwSize*** member must be initialized to the size of the structure, otherwise the method will fail with an error indicating that the parameter is invalid. All other members should be initialized to a value of zero.

Requirements

Hypertext Transfer Protocol Class Library

Transfer files between the local system and a web server, execute scripts and perform remote file management functions.

Reference

- [Class Methods](#)
- [Data Structures](#)
- [Error Codes](#)

Library Information

Class Name	CHttpClient
File Name	CSHTTPV11.DLL
Version	11.0.2218.1855
LibID	1EE620E7-5A9E-4DC3-8403-9153F19C51D9
Import Library	CSHTTPV11.LIB
Dependencies	None
Standards	RFC 1945, RFC 2616, RFC 7230, RFC 7540

Overview

The Hypertext Transfer Protocol (HTTP) is a lightweight, stateless application protocol that is used to access resources on web servers, as well as send data to those servers for processing. The library provides direct, low-level access to the server and the commands that are used to retrieve resources (i.e.: documents, images, etc.). The library also provides a simple interface for downloading resources to the local host, similar to how the FTP library can be used to download files.

In a typical session, the library is used to establish a connection, send a request (to download a resource, post data for processing, etc.), read the data returned by the server and then disconnect. It is the responsibility of the client to process the data returned by the server, depending on the type of resource that was requested.

This class supports secure, encrypted file transfers using TLS 1.2 and later versions of the protocol.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

Hypertext Transfer Protocol Class Methods

Class	Description
CHttpClient	Constructor which initializes the current instance of the class
~CHttpClient	Destructor which releases resources allocated by the class
Method	Description
AddField	Append the form field and its value to the current form
AddFile	Append the contents of the file to the current form
AddHeaders	Add one or more request headers for the current client session
AttachHandle	Attach the specified client handle to this instance of the class
AttachThread	Attach the specified client handle to another thread
Authenticate	Specify authentication information for restricted resources
Cancel	Cancel the current blocking operation
ClearForm	Remove all defined fields from the current form
ClearHeaders	Resets the the current request and response headers to their default values
CloseFile	Close the file opened on the server
Command	Send a command to the server
Connect	Connect to the specified server
ConnectUrl	Establish a client connection using the specified URL
CreateFile	Create or replace a file on the server
CreateForm	Create a new form to submit to the server
CreateSecurityCredentials	Create a new security credentials structure
DeleteFile	Remove a file from the server
DeleteField	Delete the form field and its value from the current form
DeleteHeaders	Delete all of the response or request headers for the current session
DeleteSecurityCredentials	Delete a previously created security credentials structure
DestroyForm	Destroy the current form and free the memory allocated for it
DetachHandle	Detach the handle for the current instance of this class
DisableEvents	Disable asynchronous event notification
DisableTrace	Disable logging of network function calls to the trace log
Disconnect	Disconnect from the current server
DownloadFile	Download a file from the server to the local system
EnableCompression	Enable or disable support for data compression
EnableEvents	Enable asynchronous event notification
EnableTrace	Enable logging of network function calls to a file

FreezeEvents	Suspend asynchronous event processing
GetBearerToken	Return the current OAuth 2.0 bearer token for the client session
GetContentLength	Return the size of the current resource in bytes
GetContentType	Return the content type for the current resource
GetCookie	Return information about the specified cookie
GetData	Copy the specified resource to a local buffer
GetDefaultUserAgent	Return the default user agent string included with requests
GetEncodingType	Determines which content encoding option is enabled
GetErrorString	Return a description for the specified error code
GetFile	Copy a file from the server to the local system
GetFileSize	Return the size of a file on the server
GetFileTime	Return the date and time a file on the server was last modified
GetFirstCookie	Return the first cookie set by the server
GetFirstHeader	Return the name and value of the first request or response header field
GetFormProperties	Return the properties of the specified form
GetHandle	Return the client handle used by this instance of the class
GetHeader	Return the value of the specified response header field
GetLastError	Return the last error code
GetNextCookie	Return the next cookie set by the server
GetNextHeader	Return the name and value of the next request or response header field
GetOption	Return the enabled/disabled state of a specified option
GetPriority	Return the current priority for file transfers
GetRedirectUrl	Return the URL for a redirected resource
GetResourceUrl	Return the URL for the current resource
GetResultCode	Return the result code from the previous command
GetResultString	Return the result string from the previous command
GetSecurityInformation	Return security information about the current client connection
GetStatus	Return the current client status
GetText	Download the contents of a text file or resource to a string buffer
GetTimeout	Return the number of seconds until an operation times out
GetTransferStatus	Return data transfer statistics
HttpEventProc	Callback method that processes events generated by the client
IsBlocking	Determine if the client is blocked, waiting for information
IsConnected	Determine if the client is connected to the server

IsInitialized	Determine if the class has been successfully initialized
IsReadable	Determine if data can be read from the server
IsWritable	Determine if data can be written to the server
OpenFile	Open a file on the server for reading
PatchData	Submits JSON or XML patch data to the server and returns the response
PostData	Post data from a local buffer to the server and returns the response
PostFile	Submit the contents of a local file to the server
PostJson	Post JSON formatted data to the server and returns the response
PostXml	Post XML formatted data to the server and returns the response
ProxyConnect	Establish a connection with the specified proxy server
PutData	Create a file on the server using the contents of a local buffer
PutFile	Copy a file from the local system to the server
PutText	Create a text file on the server from the contents of a string buffer
Read	Read data from the server
RegisterEvent	Register an event callback function
SetBearerToken	Set the value of the OAuth 2.0 bearer token for the client session
SetContentType	Set the content type for the request
SetCookie	Set the value of the specified cookie
SetDefaultUserAgent	Set the default user agent string included with requests
SetEncodingType	Specifies the type of encoding to be applied to data submitted to the server
SetFormProperties	Modify the properties of the current form
SetHeader	Set the value of a request header field
SetLastError	Set the last error code
SetOption	Enable or disable the specified option
SetPriority	Set the priority for file transfers
SetTimeout	Set the number of seconds until an operation times out
ShowError	Display a message box with a description of the specified error
SubmitForm	Submit the current form to the server for processing
SubmitRequest	Submit a request to the server and return the response
UploadFile	Upload a file from the local system to the server
ValidateHostName	Validate the specified host name and return the resolved IP address
ValidateUrl	Check the contents of a string to ensure it represents a valid URL
VerifyFile	Compare the size of a local file against a file stored on the server
Write	Write data to the server

CHttpClient::~CHttpClient

~CHttpClient();

The **CHttpClient** destructor releases resources allocated by the current instance of the **CHttpClient** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CHttpClient** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CHttpClient](#)

CHttpClient::AddField Method

```
INT AddField(  
    LPCTSTR lpszFieldName,  
    LPVOID lpFieldData,  
    DWORD cbFieldData  
);  
  
INT AddField(  
    LPCTSTR lpszFieldName,  
    LPCTSTR lpszFieldData  
);
```

The **AddField** method adds a new field to the current form.

Parameters

lpszFieldName

A pointer to a string which specifies the name of the field to add to the form. If this parameter is NULL or points to an empty string, then a default field name will be assigned.

lpFieldData

A pointer to the form field data. Typically this will either be a pointer to an array of bytes or a string which specifies the value for the form field. If no data is to be associated with the form field, then this argument may be NULL.

cbFieldData

An unsigned integer value which specifies the number of bytes of data in the form field. If this value is 0xFFFFFFFF (-1) then it is assumed that the *lpFieldData* parameter is a pointer to a null-terminated string. If *lpFieldData* is NULL, this value must be zero.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **AddField** method is used to add a field and its associated value to a form created using the **CreateForm** method. If the field name has already been added to the form, the previous value is deleted and replaced by the new value.

Example

```
CString strResult;  
INT nResult = 0;  
  
pClient->CreateForm(_T("/login.php"), HTTP_METHOD_POST, HTTP_FORM_ENCODED);  
pClient->AddField(_T("UserName"), lpszUserName);  
pClient->AddField(_T("Password"), lpszPassword);  
  
nResult = pClient->SubmitForm(strResult);  
pClient->DestroyForm();
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddFile](#), [ClearForm](#), [CreateForm](#), [DeleteField](#), [SubmitForm](#)

CHttpClient::AddFile Method

```
INT AddFile(  
    LPCTSTR lpszFieldName,  
    LPCTSTR lpszFileName  
);
```

The **AddFile** method adds the contents of a file to the specified form.

Parameters

lpszFieldName

A pointer to a string which specifies the name of the field to add to the form. If this parameter is NULL or points to an empty string, then a default field name will be assigned.

lpszFileName

A pointer to a string which specifies the name of the file. The contents of the file will be added to the form data that is submitted to the server.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddField](#), [ClearForm](#), [CreateForm](#), [DeleteField](#), [PostFile](#), [SubmitForm](#)

CHttpClient::AddHeaders Method

```
BOOL AddHeaders(  
    LPCTSTR lpszHeaderList  
);
```

The **AddHeaders** method adds one or more request headers for the current client session.

Parameters

lpszHeaderList

Points to a null-terminated string which specifies one or more header values which should be set for the current client session. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If a connection has not been established with a server, or the header list contains invalid values, this method returns a value of zero. To get extended error information, call the **GetLastError** method.

Remarks

The **AddHeaders** method enables your application to set one or more header values by providing a list of name/value pairs separated by a colon. Multiple header values may be provided by separating them with a newline character. This method is similar to calling the **SetHeader** method for each value. When the list of header values is parsed, extraneous whitespace is ignored; however, if the header list contains invalid text (for example, a missing colon separating a header name from its value) the method will fail and an error will be returned.

Exercise caution when providing a header list created directly from user input, such as a list of values input using a textbox control. Any header values which have been previously set by your application can be overridden by this method and may yield unpredictable results. If the service you are using requires a custom authorization header, such as an API token or other user credentials, allowing users to directly modify request header values this way can present a security risk.

Example

```
// Define a list of header values which should be included with the  
// request submitted to the server  
LPCTSTR lpszHeaderList = _T("X-API-Token: 99d2fe39-0246-4efa-98e0-4d775579fa5d\n")  
\n                        _T("X-API-UserId: someuser@domain.tld\n") \n                        _T("X-API-Version: 1.1\n")  
  
if (!pClient->AddHeaders(lpszHeaderList))  
{  
    // Unable to add the headers for this client session  
    return;  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetFirstHeader](#), [GetHeader](#), [GetNextHeader](#), [SetHeader](#)

CHttpClient::AttachHandle Method

```
VOID AttachHandle(  
    HCLIENT hClient  
);
```

The **AttachHandle** method attaches the specified client handle to the current instance of the class.

Parameters

hClient

The handle to the client session that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a client handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that client session.

If a client handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous client session from being terminated, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hClient* parameter is presumed to be a valid client handle and no checks are performed to ensure that the handle is valid. Specifying an invalid client handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[AttachThread](#), [DetachHandle](#), [GetHandle](#)

CHttpClient::AttachThread Method

```
DWORD AttachThread(  
    DWORD dwThreadId  
);
```

The **AttachThread** method attaches the specified client handle to another thread.

Parameters

dwThreadId

The ID of the thread that will become the new owner of the handle. A value of zero specifies that the current thread should become the owner of the client handle.

Return Value

If the method succeeds, the return value is the thread ID of the previous owner. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When a client handle is created, it is associated with the current thread that created it. Normally, if another thread attempts to perform an operation using that handle, an error is returned since it does not own the handle. This is used to ensure that other threads cannot interfere with an operation being performed by the owner thread. In some cases, it may be desirable for one thread in a client application to create the client handle, and then pass that handle to another worker thread. The **AttachThread** method can be used to change the ownership of the handle to the new worker thread. By preserving the return value from the method, the original owner of the handle can be restored before the worker thread terminates.

This method should be called by the new thread immediately after it has been created, and if the new thread does not release the handle itself, the ownership of the handle should be restored to the parent thread before it terminates. Under no circumstances should **AttachThread** be used to forcibly release a handle allocated by another thread while a blocking operation is in progress. To cancel an operation, use the **Cancel** method and then release the handle after the blocking method exits and control is returned to the current thread.

Note that the *dwThreadId* parameter is presumed to be a valid thread ID and no checks are performed to ensure that the thread actually exists. Specifying an invalid thread ID will orphan the client handle used by the class until the destructor is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AttachHandle](#), [Cancel](#), [Connect](#), [DetachHandle](#), [Disconnect](#), [GetHandle](#)

CHttpClient::Authenticate Method

```
INT Authenticate(
    UINT nAuthType,
    LPCTSTR lpszUserName,
    LPCTSTR lpszPassword
);

INT Authenticate(
    LPCTSTR lpszUserName,
    LPCTSTR lpszPassword
);
```

Parameters

nAuthType

An unsigned integer value which specifies the method to be used when authenticating the client. If this argument is not specified, then basic authentication will be used. The following values are recognized.

Value	Description
HTTP_AUTH_NONE	No client authentication should be performed. The <i>lpszUserName</i> and <i>lpszPassword</i> parameters are ignored and current authentication settings are cleared.
HTTP_AUTH_BASIC	The Basic authentication scheme should be used. This option is supported by all servers that support at least version 1.0 of the protocol. The user credentials are not encrypted and Basic authentication should not be used over standard (non-secure) connections. Most web services which use Basic authentication require the connection to be secure.
HTTP_AUTH_BEARER	The Bearer authentication scheme should be used. This authentication method does not require a user name and the <i>lpszPassword</i> parameter must specify the OAuth 2.0 bearer token issued by the service provider. If the access token has expired, the request will fail with an authorization error. This function will not automatically refresh an expired token.

lpszUserName

A pointer to a string that specifies the username used to authenticate the client session. This parameter may be NULL or an empty string if a user name is not required for the specified authentication type.

lpszPassword

A pointer to a string that specifies the password used to authenticate the client session.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method will set the **Authorization** request header for the client session using the credentials provided by the caller. This method will always override any custom header value

Authorization

that may have been previously set using the **SetRequestHeader** method.

If both the *lpzUserName* and *lpzPassword* parameters are NULL pointers or specify zero length strings, the current authentication type will always be set to HTTP_AUTH_NONE regardless of the value of the *nAuthType* parameter. This effectively clears the current user credentials for the client session.

If the web service requires OAuth 2.0 authentication, it is recommended you use the **SetBearerToken** method to specify the access token.

Requirements

Minimum Desktop Platform: Windows 7 (Service Pack 1)

Minimum Server Platform: Windows Server 2008 R2 (Service Pack 1)

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Connect](#), [GetBearerToken](#), [SetBearerToken](#), [SetHeader](#)

CHttpClient::Cancel Method

INT Cancel();

The **Cancel** method cancels any outstanding blocking operation in the client, causing the blocking method to fail. The application may then retry the operation or terminate the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When the **Cancel** method is called, the blocking method will not immediately fail. An internal flag is set which causes the blocking operation to exit with an error. This means that the application cannot cancel an operation and immediately perform some other operation. Instead it must allow the calling stack to unwind, returning back to the blocking operation before making any further function calls.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[IsBlocking](#)

CHttpClient::CHttpClient

CHttpClient();

The **CHttpClient** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **HttpInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::ClearForm Method

VOID ClearForm();

The **ClearForm** method clears the current form, removing all fields.

Parameters

None.

Return Value

None.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AddField](#), [AddFile](#), [CreateForm](#), [DeleteField](#), [DestroyForm](#), [SubmitForm](#)

CHttpClient::ClearHeaders Method

VOID ClearHeaders();

The **ClearHeaders** method resets the the current request and response headers to their default values.

Parameters

None.

Return Value

None.

Remarks

The **ClearHeaders** method removes all custom header values for the current client session and clears the response headers for the previous request. This method is useful when using persistent connections and you want to ensure that any custom header values from the previous request will not be included with subsequent requests made during the same session. Because this method clears all of the request headers for the client session, this means it will also remove any cookies which have been set using the **SetCookie** method.

This method will clear any authentication credentials or tokens specified for the current client session. If the next request you make requires authentication, you must provide those credentials again using the **Authenticate** or **SetBearerToken** method.

It is not necessary to use this method if the **HTTP_OPTION_KEEPALIVE** option was not specified when the connection was established. The headers for the previous request are automatically cleared when a new connection is established.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::CloseFile Method

```
INT CloseFile();
```

The **CloseFile** method flushes the internal client buffers and closes the previously opened file on the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the file is opened for writing, all buffered data is written to the server before the file is closed. This may cause the client to block until all of the data can be written. The client application should not perform any other action until the method returns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

[Command](#), [OpenFile](#), [Read](#), [Write](#)

CHttpClient::Command Method

```
INT Command(  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszResource,  
    LPBYTE lpParameter,  
    DWORD cbParameter  
);
```

```
INT Command(  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszResource,  
    LPCTSTR lpszParameter  
);
```

The **Command** method sends a command to the server, and returns the result code back to the caller. This method is typically used for extended commands not directly supported by the API.

Parameters

lpszCommand

A pointer to a string which specifies the command to be executed by the server. The following table lists the standard commands recognized by most HTTP servers. Other commands may also be used, such as those extensions used by WebDAV to edit and manage files on a server.

Command	Description
GET	Return the contents of the specified resource. This command is recognized by all servers.
HEAD	Return only header information for the specified resource. This command is recognized by servers that support at least version 1.0 of the protocol.
POST	Post data to the specified resource. This command is recognized by servers that support at least version 1.0 of the protocol.
PUT	Create or replace the specified resource on the server. This command is recognized by servers that support at least version 1.0 of the protocol. Not all servers support this command.
DELETE	Delete the specified resource from the server. This command is recognized by servers that support at least version 1.1 of the protocol. Not all servers support this command.

lpszResource

A pointer to a string which specifies the resource to be used with the command. This can be the name of a file, an executable script or any other valid resource name recognized by the server. Resource names must be absolute and include the complete path to the resource.

lpParameter

A pointer to a byte array which contains data that is to be passed to the command as one or more parameters. Typically this is used to pass additional information to a script that executes on the server. The data is encoded according to the encoding type specified for the client session. If the resource does not require any parameters, this value should be NULL.

cbParameter

Specifies the number of bytes stored in the parameter buffer. If the resource does not require any

parameters, this value should be zero.

Return Value

If the method succeeds, the return value is the result code returned by the server. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Not all servers support all of the listed commands, and some commands may require specific changes to the server configuration. In particular, the PUT and DELETE commands typically require that configuration changes be made by the site administrator. All servers will support the use of the GET command, and all servers that support at least version 1.0 of the protocol will support the POST command.

If the *lpSzResource* parameter specifies a path that contains reserved or restricted characters, such as a space, it will automatically be URL encoded by the library.

It is permissible to include a query string in the resource name specified by the *lpSzResource* parameter. Query strings begin with a question mark, and then are followed by one or more name/value pairs separated by an equal sign. For example, the following resource includes a query string:

```
/cgi-bin/test.cgi?field1=value1&field2=value2
```

In this case, the query string is "?field1=value1&field2=value2". If the query string contains reserved or restricted characters, such as spaces, then it will be automatically URL encoded prior to being sent to the server. If additional resource data is specified in the *lpParameter* argument along with a query string in the resource name, the action taken by the library depends on the command being sent. If the command is a POST or PUT command, then query string is included with command request to the server and the parameter data is sent separately. For example, if the POST command was used, the script running on the server would see that both query data and form data has been provided to it. However, if any other command is specified, the parameter data is simply appended to the query string.

The *lpParameter* argument is used to pass additional information to the server when a resource is requested. This is most commonly used to provide information to scripts, similar to how arguments are used when executing a program from the command line. Unless the POST command is being executed, the data in the buffer will automatically be encoded using the current encoding mechanism specified for the client. By default, the data is URL encoded, which means that any spaces and non-printable characters are converted to printable characters before submitted to the server. The type of encoding that is performed can be set by calling the **SetEncodingType** method. Although the default encoding is appropriate for most applications, those that submit XML formatted data may need to change the encoding type.

Only one request may be in progress at one time for each client session. Use the **CloseFile** method to terminate the request after all of the data has been read from the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::Connect Method

```
BOOL Connect(  
    LPCTSTR lpszRemoteHost,  
    UINT nRemotePort,  
    UINT nTimeout,  
    DWORD dwOptions,  
    DWORD dwVersion  
);
```

The **Connect** method is used to establish a connection with the specified server.

Parameters

lpszRemoteHost

A pointer to the name of the server to connect to. This may be a fully-qualified domain name or an IP address.

nRemotePort

The port number the server is listening on. A value of zero specifies that the default port number should be used. For standard connections, the default port number is 80. For secure connections, the default port number is 443.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_KEEPALIVE	This instructs the server to maintain a persistent connection between requests. This can improve performance because it eliminates the need to establish a separate connection for each resource that is requested. If the server does not support the keep-alive option, the client will automatically reconnect when each resource is requested. Although it will not provide any performance benefits, this allows the option to be used with all servers.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.

HTTP_OPTION_PROXY	This option specifies the client should use the default proxy configuration for the local system. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. The local proxy configuration can be changed in the system settings or control panel.
HTTP_OPTION_ERRORDATA	This option specifies the client should return the content of an error response from the server, rather than returning an error code. Note that this option will disable automatic resource redirection, and should not be used with HTTP_OPTION_REDIRECT.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server. An application can provide its own custom user agent value using the SetHeader method.
HTTP_OPTION_HTTP2	This option specifies the client should establish a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol. The value of the <i>dwVersion</i> parameter will be ignored when this option is used.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.

HTTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
HTTP_OPTION_FREETHREAD	This option specifies that this instance of the class may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the class instance is synchronized across multiple threads.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.

dwVersion

The requested protocol version used when sending requests to the server. The high word should specify the major version, and the low word should specify the minor version number. The HTTPVERSION macro can be used to create a version value and the following values are defined:

Value	Description
HTTP_VERSION_DEFAULT	The client should use the default protocol version for this session. This is the same as specifying HTTP_VERSION_11 and is recommended to ensure the broadest compatibility with most servers.
HTTP_VERSION_09	The client should use the original one-line protocol which includes no version number and no request header block. This version has been deprecated and should only be used with legacy servers which do not support the protocol standard. This version of the protocol does not support virtual hosts and is not supported by most modern web services.
HTTP_VERSION_10	The client should use the HTTP/1.0 protocol standard originally defined in RFC 1945. This version of the protocol supports the use of request header blocks, however it does not support persistent connections or chunked data and has limited cache control mechanisms.
HTTP_VERSION_11	The client should use the HTTP/1.1 protocol standard defined in RFC 2616 and RFC 7230. This is the most widely used version of the protocol and is the default for client connections. It is recommended most applications use this version.
HTTP_VERSION_20	The client should use the HTTP/2 protocol standard defined in RFC 7540. This protocol version is a significant change from

	previous versions and can provide improved performance with header compression and optimizing how requests are serviced. If the client or server does not support HTTP/2, the client will automatically attempt to use an earlier version of the protocol.
--	------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **Connect** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

The *dwOptions* argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the HTTP_OPTION_FREETHREAD option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

If the HTTP_OPTION_KEEPALIVE option is specified and the server does not support persistent connections, the client will automatically reconnect when each resource is requested. Although it will not provide any performance benefits, this allows the option to be used with all servers. This option is automatically enabled when using HTTP/2.

Under some circumstances, a server may forcibly close or abort a connection if the request fails. For example, this can happen when a malformed request is submitted to the server or a server-side error occurs. When this happens, the application will need to disconnect from the server and establish a new connection, even if the keep-alive option has been specified.

Applications should use HTTP_VERSION_DEFAULT as the value for the *dwVersion* parameter. This will default to an appropriate version for the Windows platform and ensures the broadest compatibility with most servers. If your application specifies HTTP_VERSION_20, a secure connection using TLS 1.2 or later will always be used. The minimum required platform for HTTP/2 support is Windows 10 (Build 1903) or Windows Server 2019. Earlier versions of the Schannel SSP do not support the features required for a secure HTTP/2 connection.

If your application requests a HTTP/2 connection and the server only accepts earlier versions of the protocol, the client will attempt to automatically downgrade the request to HTTP/1.1. If a connection using an earlier version of the protocol cannot be established, the method will fail and return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[ConnectUrl](#), [Disconnect](#), [IsConnected](#), [ProxyConnect](#)

CHttpClient::ConnectUrl Method

```
BOOL ConnectUrl(  
    LPCTSTR lpszUrl,  
    UINT nTimeout,  
    DWORD dwOptions  
);
```

The **ConnectUrl** method establishes a connection with the specified server using a URL.

Parameters

lpszUrl

A pointer to a string which specifies the URL for the server. The URL must follow the conventions for the Hypertext Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_KEEPALIVE	This instructs the server to maintain a persistent connection between requests. This can improve performance because it eliminates the need to establish a separate connection for each resource that is requested.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_PROXY	This option specifies the client should use the default proxy configuration for the local system. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. The local proxy configuration can be changed in the system settings or control panel.
HTTP_OPTION_ERRORDATA	This option specifies the client should return the

	content of an error response from the server, rather than returning an error code. Note that this option will disable automatic resource redirection, and should not be used with HTTP_OPTION_REDIRECT.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server. An application can provide its own custom user agent value using the SetHeader method.
HTTP_OPTION_HTTP2	This option specifies the client should attempt a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
HTTP_OPTION_FREETHREAD	This option specifies that this instance of the class may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the class instance is synchronized across multiple threads.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller files being uploaded or downloaded using fast network connections.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **ConnectUrl** method uses an HTTP URL to establish a connection with a server. The URL must be in the following format:

```
[http|https]://[username : password] @[hostname [:port] / [path / ...]  
[filename]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "http" scheme is used and the HTTP_OPTION_SECURE option is specified, that option will be ignored. To establish a secure connection, the "https" scheme must be specified. The **ValidateUrl** method can be used to verify that a URL is valid prior to calling this method.

The **ConnectUrl** method is designed to provide a simpler, more convenient interface to establishing a connection with a server. However, complex connections such as those using a specific proxy server or a secure connection which uses a client certificate will require the program to use the lower-level connection methods. If you only need to upload or download a file using a URL, then refer to the **UploadFile** and **DownloadFile** methods.

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **ConnectUrl** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

The *dwOptions* argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the HTTP_OPTION_FREETHREAD option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

If the HTTP_OPTION_KEEPALIVE option is specified and the server does not support persistent connections, the client will automatically reconnect when each resource is requested. Although it will not provide any performance benefits, this allows the option to be used with all servers. This option is automatically enabled when using HTTP/2.

If your application specifies the HTTP_OPTION_HTTP2 option, a secure connection using TLS 1.2 or later will always be used. The minimum required platform for HTTP/2 support is Windows 10 (Build 1903) or Windows Server 2019. Earlier versions of Windows do not support the features required for a secure HTTP/2 connection. If the server only accepts earlier versions of the protocol, the client will attempt to automatically downgrade the request to HTTP/1.1. If a connection using an earlier version of the protocol cannot be established, the function will fail and return INVALID_CLIENT.

Example

```
CHttpClient httpClient;
```

```
if (!httpClient.ConnectUrl(_T("http://sockettools.com/")))  
{  
    httpClient.ShowError();  
    return;  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[Connect](#), [Disconnect](#), [DownloadFile](#), [UploadFile](#), [ValidateUrl](#)

CHttpClient::CreateFile Method

```
INT CreateFile(  
    LPCTSTR lpszRemoteFile,  
    DWORD dwFileLength  
);
```

The **CreateFile** method creates the specified file on the server.

Parameters

lpszRemoteFile

Points to a string that specifies the name of the file being created on the server. The client must have the appropriate access rights to create the file or an error will be returned.

dwFileLength

Specifies the length of the file that will be created on the server. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **CreateFile** method uses the PUT command to create the file. The server must support this command and the user must have the appropriate permission to create the specified file. If this method is successful, the client should then use the **Write** method to send the contents of the file to the server. Once all of the data has been written, the **CloseFile** method should be called to close the file and complete the operation. Note that this method is typically only accepted by servers that support version 1.1 of the protocol or later.

When using **Write** to send the contents of the file to the server, it is recommended that the data be written in logical blocks that are no larger than 8,192 bytes in size. Attempting to write very large amounts of data in a single call can either cause the thread to block or, in the case of an asynchronous connection, return an error if the internal buffers cannot accommodate all of the data. To send the entire contents of a file in a single method call, use the **PutData** method instead of calling **CreateFile**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::CreateForm Method

```
BOOL CreateForm(  
    LPCTSTR lpszAction,  
    UINT nFormMethod,  
    UINT nFormType  
);
```

The **CreateForm** method creates a new form for use with the other form-related functions.

Parameters

lpszAction

A pointer to a string which specifies the name of the resource that the form data will be submitted to. Typically this is the name of a script that is executed on the server.

nFormMethod

An unsigned integer value which specifies how the form data will be submitted to the server. This parameter may be one of the following values:

Value	Description
HTTP_METHOD_DEFAULT	The form data should be submitted using the default method, using the GET command.
HTTP_METHOD_GET	The form data should be submitted using the GET command. This method should be used when the amount of form data is relatively small. If the total amount of form data exceeds 2048 bytes, it is recommended that the POST method be used instead.
HTTP_METHOD_POST	The form data should be submitted using the POST command. This is the preferred method of submitting larger amounts of form data. If the total amount of form data exceeds 2048 bytes, it is recommended that the POST method be used.

nFormType

An unsigned integer value which specifies the type of form and how the data will be encoded when it is submitted to the server. This parameter may be one of the following values:

Value	Description
HTTP_FORM_DEFAULT	The form data should be submitted using the default encoding method.
HTTP_FORM_ENCODED	The form data should be submitted as URL encoded values. This is typically used when the GET method is used to submit the data to the server.
HTTP_FORM_MULTIPART	The form data should be submitted as multipart form data. This is typically used when the POST method is used to submit a file to the server. Note that the script must understand how to process multipart form data if this form type is specified.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To

get extended error information, call **GetLastError**.

Remarks

The **CreateForm** method is used to create a new form that will be populated with values and then submitted to the server for processing. When the form is no longer needed, it should be destroyed using the **DestroyForm** function.

Example

```
CString strResult;  
INT nResult = 0;  
  
pClient->CreateForm(_T("/login.php"), HTTP_METHOD_POST, HTTP_FORM_ENCODED);  
pClient->AddField(_T("UserName"), lpszUserName);  
pClient->AddField(_T("Password"), lpszPassword);  
  
nResult = pClient->SubmitForm(strResult);  
pClient->DestroyForm();
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddField](#), [AddFile](#), [ClearForm](#), [DeleteField](#), [DestroyForm](#), [SubmitForm](#)

CHttpClient::CreateSecurityCredentials Method

```
BOOL CreateSecurityCredentials(  
    DWORD dwProtocol,  
    DWORD dwOptions,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName  
);  
  
BOOL CreateSecurityCredentials(  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName  
);  
  
BOOL CreateSecurityCredentials(  
    LPCTSTR lpszCertName  
);
```

The **CreateSecurityCredentials** method creates security credentials for the client session.

Parameters

dwProtocol

A bitmask of supported security protocols. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows

	Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

dwOptions

A value which specifies one or more options. This member is constructed by using a bitwise operator with any of the following values:

Value	Description
CREDENTIAL_STORE_CURRENT_USER	The library will attempt to open a store for the current user using the certificate store name provided in this structure. If no options are specified, then this is the default behavior.
CREDENTIAL_STORE_LOCAL_MACHINE	The library will attempt to open a local machine store using the certificate store name provided in this structure. If this option is specified, the library will always search for a local machine store before searching for the store by that name for the current user.
CREDENTIAL_STORE_FILENAME	The certificate store name is a file that contains the certificate and private key that will be used.

lpzUserName

A pointer to a string which specifies the certificate owner's username. A value of NULL specifies that no username is required. Currently this parameter is not used and any value specified will be ignored.

lpzPassword

A pointer to a string which specifies the certificate owner's password. A value of NULL specifies that no password is required. This parameter is only used if a PKCS #12 (PFX) certificate file is specified and that certificate has been secured with a password. This value will be ignored the current user or local machine certificate store is specified.

lpzCertStore

A pointer to a string which specifies the name of the certificate store to open. A certificate store is a

collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpzCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The method will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the method will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the method will return an error indicating that the certificate could not be found.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

A client application only needs to call this method if the server requires that the client provide a certificate as part of the process of negotiating the secure session. If a certificate is required, note that it must have a private key associated with it. Attempting to use a certificate that does not have a private key will result in an error during the connection process indicating that the client credentials could not be established.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user, or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The **dwOptions** parameter should be set to CREDENTIAL_STORE_FILENAME and the **lpzCertStore** parameter should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. If a password was specified when the certificate was

created, it must be provided in the *lpzPassword* parameter or the library will be unable to access the certificate.

Note that the *lpzUserName* and *lpzPassword* parameters are optional values which are used to access the certificate store or client certificate. They are not the credentials which are used when establishing the connection with the remote host or authenticating the client session. In most cases, these parameters can be NULL or omitted.

Example

```
pClient->CreateSecurityCredentials(  
    SECURITY_PROTOCOL_DEFAULT,  
    0,  
    NULL,  
    NULL,  
    lpzCertStore,  
    lpzCertName);  
  
bConnected = pClient->Connect(lpzHostName,  
    HTTP_PORT_SECURE,  
    HTTP_TIMEOUT,  
    HTTP_OPTION_SECURE);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::DeleteField Method

```
INT DeleteField(  
    LPCTSTR lpszFieldName  
);
```

The **DeleteField** method deletes the specified field from the current form.

Parameters

lpszFieldName

Points to a string that specifies the name of the field to delete.

Return Value

If the function succeeds, the return value is zero. If the function fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AddField](#), [AddFile](#), [ClearForm](#), [CreateForm](#), [SubmitForm](#)

CHttpClient::DeleteFile Method

```
INT DeleteFile(  
    LPCTSTR lpszFileName  
);
```

The **DeleteFile** method deletes the specified file from the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file to delete. The file pathing and name conventions must be that of the server.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the DELETE command to delete the specified file from the server. The server must be configured to support this command, and client must have the appropriate permission to delete the file, or an error will be returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetFile](#), [PutFile](#)

CHttpClient::DeleteHeaders Method

```
BOOL DeleteHeaders(  
    UINT nHeaderType  
);
```

Delete all of the response or request headers for the current session.

Parameters

nHeaderType

Specifies the type of header to delete. It may be one of the following values:

Value	Description
HTTP_HEADERS_REQUEST	Delete all of the request headers that have been set for the next request sent to the server. This will clear all of the header values that were set using the SetRequestHeader method.
HTTP_HEADERS_RESPONSE	Delete all of the headers that were set in response to the previous request. A call to the GetResponseHeader method to obtain a specific header value will fail after this method returns.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **DeleteHeaders** method will release the memory allocated for the request or response headers for the current session. This method is typically used to clear all of the current request headers so that the application may create a new set of headers when a persistent connection is being used. The memory allocated for the request and response headers is normally released when the session handle is closed by calling the **Disconnect** method.

Whenever a request for a resource is sent to the server, the response headers from the previous request are automatically cleared. It is not necessary for an application to call the **DeleteHeaders** method to delete the response headers prior to each request.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** cshttpv11.lib

CHttpClient::DeleteSecurityCredentials Method

VOID DeleteSecurityCredentials();

The **DeleteSecurityCredentials** method releases the security credentials for the current session.

Parameters

None.

Return Value

None.

Remarks

This method can be used to release the memory allocated to the client or server credentials after a secure connection has been terminated. The security credentials are released when the class destructor is called, so it is normally not required that the application explicitly call this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CreateSecurityCredentials](#)

CHttpClient::DestroyForm Method

VOID DestroyForm();

The **DestroyForm** method destroys the current form, releasing the memory allocated for it.

Parameters

None.

Return Value

None.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AddField](#), [AddFile](#), [ClearForm](#), [CreateForm](#), [DeleteField](#), [SubmitForm](#)

CHttpClient::DetachHandle Method

HCLIENT DetachHandle();

The **DetachHandle** method detaches the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to detach a client handle created by the class for use with the SocketTools API. Once the client handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `cshttpv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CHttpClient::DisableEvents Method

INT DisableEvents();

The **DisableEvents** method disables the event notification mechanism, preventing subsequent event notification messages from being posted to the application's message queue.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **DisableEvents** method is used to disable event message posting for the specified client session. Although this will immediately prevent any new events from being generated, it is possible that messages could be waiting in the message queue. Therefore, an application must be prepared to handle client event messages after this method has been called.

This method is automatically called if the client has event notification enabled, and the **Disconnect** method is called. The same issues regarding outstanding event messages also applies in this situation, requiring that the application handle event messages that may reference a client handle that is no longer valid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::DownloadFile Method

```
BOOL DownloadFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    UINT nTimeout  
    DWORD dwOptions  
    LPHTTPTRANSFERSTATUS lpStatus  
    HTTPEVENTPROC lpEventProc  
    DWORD_PTR dwParam  
);
```

The **DownloadFile** method downloads the specified file from the server to the local system.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be created, overwritten or appended to. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the complete URL of the file to be downloaded. The URL must follow the conventions for the File Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response before failing the operation. A value of zero specifies that the default timeout period of sixty seconds will be used.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_PROXY	This option specifies the client should use the default proxy configuration for the local system. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. The local proxy configuration can be changed using the system Control Panel.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a

	User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server. If this option is not specified, a default user agent string will be included with the request.
HTTP_OPTION_HTTP2	This option specifies the client should attempt a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
HTTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.

A pointer to an **HTTPTRANSFERSTATUS** structure which contains information about the status of the current file transfer. If this information is not required, a NULL pointer may be specified as the parameter.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **EventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **DownloadFile** method provides a convenient way for an application to download a file in a single method call. Based on the connection information specified in the URL, it will connect to the server, authenticate the session and then download the file to the local system. The URL must be complete, and specify either a standard or secure HTTP scheme:

```
[http|https]://[username : password] @[hostname [:port] / [path / ...]  
[filename]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "http" scheme is used and the **HTTP_OPTION_SECURE** option is specified, that option will be ignored. To establish a secure connection, the "https" scheme must be specified.

If your application requests a HTTP/2 connection and the server only accepts earlier versions of the protocol, the client will attempt to automatically downgrade the request to HTTP/1.1. If a connection using an earlier version of the protocol cannot be established, the method will fail and return a value of zero.

The **lpStatus** parameter can be used by the application to determine the final status of the transfer, including the total number of bytes copied, the amount of time elapsed and other information related to the transfer process. If this information isn't needed, then this parameter may be specified as NULL.

The **lpEventProc** parameter specifies a pointer to a function which will be periodically called during the file transfer process. This can be used to check the status of the transfer by calling **GetTransferStatus** and then update the program's user interface. For example, the callback function could calculate the percentage for how much of the file has been transferred and then update a progress bar control. The **dwParam** parameter is used in conjunction with the event handler and specifies a user-defined value that is passed to the callback function. One common use in a C++ program is to pass the **this** pointer as the value, and then cast it back to an object pointer inside the callback function. If no event handler is required, then a NULL pointer can be specified as the value for **lpEventProc** and the **dwParam** parameter will be ignored.

The **DownloadFile** method is designed to provide a simpler interface for downloading a file. However, complex connections such as those using a specific proxy server or a secure connection which uses a client certificate will require the program to establish the connection using **Connect** and then use **GetFile** to download the file.

Example

```
CHttpClient httpClient;  
CString strLocalFile = _T("c:\\temp\\database.mdb");  
CString strFileURL = _T("http://www.example.com/updates/database.mdb");  
  
// Download the file using the specified URL  
if (!httpClient.DownloadFile(strLocalFile, strFileURL))  
{  
    httpClient.ShowError();  
    return;  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpClient::EnableCompression Method

```
INT EnableCompression(  
    BOOL bEnable  
);
```

The **EnableCompression** method enables or disables support for data compression.

Parameters

bEnable

An optional boolean value which specifies if data compression should be enabled or disabled. A non-zero value enables compression, while a value of zero will disable compression. If this parameter is omitted, compression will be enabled.

Return Value

If the function succeeds, the return value is zero. If the function fails, the return value is HTTP_ERROR. To get extended error information, call **HttpGetLastError**.

Remarks

The **HttpEnableCompression** method is used to indicate to the server whether or not it is acceptable to compress the data that is returned to the client. If compression is enabled, the client will advertise that it will accept compressed data by setting the **Accept-Encoding** request header. The server will decide whether a resource being requested can be compressed. If the data is compressed, the library will automatically expand the data before returning it to the caller.

Enabling compression does not guarantee that the data returned by the server will actually be compressed, it only informs the server that the client is willing to accept compressed data. Whether or not a particular resource is compressed depends on the server configuration, and the server may decide to only compress certain types of resources, such as text files. Disabling compression informs the server that the client is not willing to accept compressed data; this is the default.

If the **SetHeader** method is used to explicitly set the **Accept-Encoding** header to request compressed data and compression is not enabled, the library will not attempt to automatically expand the data returned by the server. In this case, the raw compressed data will be returned to the caller and the application is responsible for processing it. This behavior is by design to maintain backwards compatibility with previous versions of the library that did not have internal support for compression.

To determine if the server compressed the data returned to the client, use the **GetHeader** method to get the value of the **Content-Encoding** header. If the header is defined, the value specifies the compression method used, otherwise the data was not compressed.

Enabling compression is only meaningful when downloading files from a server that supports file compression. It has no effect on file uploads.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

[GetData](#), [GetFile](#), [GetHeader](#), [GetText](#), [SetHeader](#)

CHttpClient::EnableEvents Method

```
INT EnableEvents(  
    HWND hEventWnd,  
    UINT uEventMsg  
);
```

The **EnableEvents** method enables event notifications using Windows messages.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Applications should use the **RegisterEvent** method to register an event handler which is invoked when an event occurs.

Parameters

hEventWnd

Handle to the window which will receive the client notification messages. This parameter must specify a valid window handle. If a NULL handle is specified, event notification will be disabled.

uEventMsg

The message that is received when a client event occurs. This value must be greater than 1024.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **EnableEvents** method is used to request that notification messages be posted to the specified window whenever a client event occurs. This allows an application to monitor the status of different client operations, such as a file transfer.

The *wParam* argument will contain the client handle, the low word of the *lParam* argument will contain the event ID, and the high word will contain any error code. If no error has occurred, the high word will always have a value of zero. The following events may be generated:

Value	Description
HTTP_EVENT_CONNECT	The connection to the server has completed. The high word of the <i>lParam</i> parameter should be checked, since this notification message will be posted if an error has occurred.
HTTP_EVENT_DISCONNECT	The server has closed the connection to the client. The client should read any remaining data and disconnect.
HTTP_EVENT_READ	Data is available to read by the calling process. No additional messages will be posted until the client has read at least some of the data. This event is only generated if the client is in asynchronous mode.
HTTP_EVENT_WRITE	The client can now write data. This notification is sent after a connection has been established, or after a previous attempt to write data has failed because it would result in a blocking operation. This

	event is only generated if the client is in asynchronous mode.
HTTP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
HTTP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.
HTTP_EVENT_COMMAND	A command has been issued by the client and the server response has been received and processed. This event can be used to log the result codes and messages returned by the server in response to actions taken by the client.
HTTP_EVENT_PROGRESS	The client is in the process of sending or receiving a file on the data channel. This event is called periodically during a transfer so that the client can update any user interface components such as a status control or progress bar.

It is not required that the client be placed in asynchronous mode in order to receive command and progress event notifications. To disable event notification, call the **DisableEvents** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

[DisableEvents](#), [RegisterEvent](#)

CHttpClient::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of socket function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the server.

Logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

When logging is enabled for HTTP/2 client sessions, it is normal to see HTTP/1.1 in the request and server response. HTTP/2 is a binary protocol and the request and response header blocks emulate a standard HTTP/1.1 text response for backwards compatibility. Applications running on the server

should work in the same way regardless of which protocol version is selected, however it is possible to check the server environment to determine which version of HTTP was used with the request.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpClient::FreezeEvents Method

```
INT FreezeEvents(  
    BOOL bFreeze  
);
```

The **FreezeEvents** method is used to suspend and resume event handling by the client.

Parameters

bFreeze

A non-zero value specifies that event handling should be suspended by the client. A zero value specifies that event handling should be resumed.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method should be used when the application does not want to process events, such as when a modal dialog is being displayed. When events are suspended, all client events are queued. If events are re-enabled at a later point, those queued events will be sent to the application for processing. Note that only one of each event will be generated. For example, if the client has suspended event handling, and four read events occur, once event handling is resumed only one of those read events will be posted to the client. This prevents the application from being flooded by a potentially large number of queued events.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DisableEvents](#), [EnableEvents](#), [RegisterEvent](#)

CHttpClient::GetBearerToken Method

```
INT GetBearerToken(  
    LPTSTR lpszBearerToken,  
    INT nMaxLength  
);  
  
INT GetBearerToken(  
    CString& strBearerToken  
);
```

The **GetBearerToken** method returns the OAuth 2.0 bearer token used to authenticate the client session with a web service.

Parameters

lpszBearerToken

A pointer to a string buffer which will contain the bearer token when the method returns. The string will be null terminated and the buffer must be large enough to accommodate the entire bearer token or the method will fail. This parameter cannot be a NULL pointer. An alternate version of this method accepts a **CString** object.

nMaxLength

The maximum number of characters that may be copied into the string buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the length of the bearer token string. A return value of zero indicates that no bearer token has been specified. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method returns the bearer token which was previously set by a call to **SetBearerToken**. Bearer tokens can be very long strings and do not contain any human readable information. For Google services, these tokens are usually about 180 characters in length. For Microsoft services, their bearer tokens are typically 1,200 characters in length. It is recommended that you provide a buffer size of at least 2,000 characters.

Your application should not store the bearer tokens provided by a web service. These tokens are short-lived and typically only valid for about an hour. If the token has expired, the authorization to access the resource will fail and it must be refreshed. The refresh tokens used to acquire a new bearer token should be stored and they are typically valid for a period of months.

Requirements

Minimum Desktop Platform: Windows 7 (Service Pack 1)

Minimum Server Platform: Windows Server 2008 R2 (Service Pack 1)

Header File: ctools11.h

Import Library: cshttpv11.lib

[Authenticate](#), [SetBearerToken](#)

CHttpClient::GetContentLength Method

```
BOOL GetContentLength(  
    LPDWORD lpLength  
);
```

```
BOOL GetContentLength(  
    ULARGE_INTEGER *lpLength  
);
```

The **GetContentLength** method returns the size of the current resource in bytes.

Parameters

hClient

Handle to the client session.

lpLength

A pointer to a unsigned integer which will contain the content length for the current resource. This value will be initialized to zero and updated with the length when the method returns. If it's possible the server will return more than 4GiB of data to the client, this parameter should point to an unsigned 64-bit integer.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

When this method is called after a GET or POST request has completed, the *lpLength* parameter will contain the total number of bytes returned by the server. If this method is called while a request is being processed (for example, from within an event handler), it will return the value of the Content-Length response header provided by the server.

Most servers will only include a Content-Length header in the response for static resources like documents or image files. For other types of resources where the response payload is generated dynamically, such as server-side scripts, servers typically use "chunked" output and there is no Content-Length header. The server may also not provide a file size for HTML documents which use server side includes (SSI) because that content is also dynamically created by the server. In this case, the content length can only be determined after the request has completed.

This method should only be used after a request has completed and will not return a value for dynamic resources as they are being retrieved from the server. To obtain the current number of bytes copied from within an event handler, use the **GetTransferStatus** method.

If the content type for the current resource is textual, the content length reported by the server may be different than what is stored on the local system due to different end-of-line character conventions. For example, on Windows the end of a line of text is indicated by a carriage-return and linefeed pair, while on Linux the end-of-line is indicated by a single linefeed. Depending on the options specified when the request is made, text returned by the server may be normalized for the Windows platform.

This method does not use the HEAD command to request the size of a document on the server. It will only return the content length of a resource which has already been requested, typically after using methods such as **GetText** or **PostXml**. To ask the server for the size of document without downloading the contents of that document, use the **GetFileSize** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

[GetContentType](#), [GetFileSize](#), [GetHeader](#), [GetTransferStatus](#), [SetContentType](#)

CHttpClient::GetContentType Method

```
INT GetContentType(  
    LPTSTR lpszContentType,  
    INT nMaxLength  
);
```

The **GetContentType** method returns the content type for the current resource.

Parameters

hClient

Handle to the client session.

lpszContentType

A pointer to a buffer which will contain the MIME content type of the resource returned by the web server. The buffer must be large enough to contain the entire content type string including the terminating null character. This parameter is optional and may be NULL if the information is not required.

nMaxLength

An integer value which specifies the maximum number of characters which can be copied into the buffer. If the *lpszContentType* parameter is NULL, this value must be zero.

Return Value

If the method succeeds, the value indicates the type of resource returned by the server. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Value	Description
HTTP_CONTENT_UNKNOWN	The content type for the resource could not be determined. This can occur if the content type returned by the server does not match a known value, such as an experimental or non-standard content type.
HTTP_CONTENT_BINARY	Application specific binary data which doesn't explicitly fall into any of the other standard MIME types. The most common type for binary data is application/octet-stream which can represent any type of data. Other examples are application/pdf and application/zip.
HTTP_CONTENT_TEXT	Textual data which can include plain text, HTML documents, XML, comma-separated value (CSV) data or any other human readable text formats. Examples are text/plain and text/html.
HTTP_CONTENT_AUDIO	Audio data which can include MPEG audio and Windows Media formats. Examples are audio/mpeg, audio/mp4 and audio/x-ms-wma.
HTTP_CONTENT_IMAGE	Image data which can include GIF, JPEG and PNG image formats. Examples are image/gif and image/jpeg.
HTTP_CONTENT_MESSAGE	A content type which specifies the response includes other messages, typically email messages in a standard MIME format. This content type is not commonly used with web

	services.
HTTP_CONTENT_MULTIPART	A content type which includes multiple types of data in a single response. The payload will typically be encoded text and the contents will need to be decoded to extract any binary data included in the message.
HTTP_CONTENT_VIDEO	Video data which can include MP4 movies or Window Media format video. Examples are video/mp4 and video/x-ms-wmv.
HTTP_CONTENT_FONT	Font data which can include TrueType and OpenType fonts. Examples are font/ttf and font/otf.
HTTP_CONTENT_MODEL	Model data for 3D objects and scenes, such as those used with the Virtual Reality Modeling Language (VRML). Examples are model/3mf and model/vrml.

Remarks

This method does not examine the contents of the payload returned by the server and only returns a value based on the Content-Type response header. If the web server does not recognize the data format of the resource it is returning, it should identify it as **application/octet-stream** and the content type would be returned as HTTP_CONTENT_BINARY. However, some servers incorrectly return unrecognized formats as text/plain, causing the payload to be identified as human-readable text rather than binary data.

Some servers will return a content type of **text/plain** for JSON responses and others will use the IANA standard type of **application/json**. To ensure consistency with these two content types, this method will always return MIME_CONTENT_TEXT for JSON responses.

CHttpClient::GetCookie Method

```
BOOL GetCookie(  
    LPCTSTR lpszCookieName,  
    LPTSTR lpszCookieValue,  
    INT nCookieValue,  
    LPTSTR lpszCookiePath,  
    INT nCookiePath,  
    LPTSTR lpszCookieDomain,  
    INT nCookieDomain,  
    LPSYSTEMTIME lpCookieExpires,  
    LPDWORD lpdwCookieFlags  
);
```

```
BOOL GetCookie(  
    LPCTSTR lpszCookieName,  
    CString& strCookieValue,  
    CString& strCookiePath,  
    CString& lpszCookieDomain,  
    LPSYSTEMTIME lpCookieExpires,  
    LPDWORD lpdwCookieFlags  
);
```

```
BOOL GetCookie(  
    LPCTSTR lpszCookieName,  
    CString& strCookieValue  
);
```

The **GetCookie** method returns information about a cookie set by the server.

Parameters

lpszCookieName

A pointer to a string which specifies the name of the cookie to return information about.

lpszCookieValue

A pointer to a string buffer that will contain the value of the cookie. If this information is not required, a NULL pointer may be specified.

nCookieValue

The maximum number of characters that may be copied into the buffer specified by the *lpszCookieValue* parameter, including the terminating null character.

lpszCookiePath

A pointer to a string buffer that will contain the cookie path. If this information is not required, a NULL pointer may be specified.

nCookiePath

The maximum number of characters that may be copied into the buffer specified by the *lpszCookiePath* parameter, including the terminating null character.

lpszCookieDomain

A pointer to a string buffer that will contain the cookie domain. If this information is not required, a NULL pointer may be specified.

nCookieDomain

The maximum number of characters that may be copied into the buffer specified by the

lpzCookieDomain parameter, including the terminating null character.

lpCookieExpires

A pointer to a [SYSTEMTIME](#) structure which specifies the date and time that the cookie expires. If this information is not required, a NULL pointer may be specified.

lpdwCookieFlags

One or more bit flags which specify status information about the cookie. A value of zero indicates that there are no special status flags for the cookie. This parameter may be NULL if the information is not required. The following values are currently defined:

Value	Description
HTTP_COOKIE_SECURE	This flag specifies that the cookie should only be provided to the server if the connection is secure.
HTTP_COOKIE_SESSION	This flag specifies that the cookie should only be used for the current application session and should not be stored permanently on the local system.

Return Value

If the method succeeds, the return value is non-zero. If the specified cookie does not exist or method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The Hypertext Transfer Protocol uses special tokens called "cookies" to maintain persistent state information between requests for a resource. These cookies are exchanged between the client and server by setting specific header fields. When a server wants the client to use a cookie, it will include a header field named Set-Cookie in the response header when the client requests a resource. The client can then take this cookie and store it, either temporarily in memory or permanently in a file on the local system. The next time that the client requests a resource from that server, it can send the cookie back to the server by setting the Cookie header field. The **GetCookie** method searches for a cookie set by the server in the Set-Cookie header field. The **SetCookie** method creates or modifies the Cookie header field for the next resource requested by the client.

There are two general types of cookies that are used by servers. Session cookies exist only for the duration of the client session; they are stored in memory and not saved in any kind of permanent storage. When the client application terminates, session cookies are deleted and no longer used. Persistent cookies are stored on the local system and are used by the client until their expiration time. It is the responsibility of the client application to store persistent cookies; applications may use a flat text file, a database or any other storage method available.

In addition to the cookie name and value, the server may return additional information about the cookie which the client should use to determine if it should send the cookie back to the server:

The **cookie path** specifies a path for the resources where the cookie should be used. For example, a path of "/" indicates that the cookie should be provided for all resources requested from the server. A path of "/data" would mean that the cookie should be included if the resource is found in the /data folder or a sub-folder, such as /data/projections.asp. However, the cookie would not be provided if the resource /info/status.asp was requested, since it is not in the /data path.

The **cookie domain** specifies the domain for which the cookie should be used. Matches are made by comparing the name of the server against the domain name specified in the cookie. If the domain is example.com, then any server in the example.com domain would match; for

example, both `shipping.example.com` and `orders.example.com` would match the domain value. However, if the cookie domain was `orders.example.com`, then the cookie would only be sent if the resource was requested from `orders.example.com`, not if the resource was located on `shipping.example.com` or `www.example.com`.

The ***cookie expiration*** specifies the date and time that the cookie should be deleted and no longer sent when a resource is requested from the server. This is only valid for persistent cookies, since session cookies are automatically deleted when the client application terminates. The time is always expressed as Coordinated Universal Time.

The ***cookie flags*** provide additional information about the cookie. In some cases, a cookie should only be submitted to the server if the resource is requested using a secure connection. In this case, the bit flag `HTTP_COOKIE_SECURE` will be set.

It is the responsibility of the client application to determine if a cookie meets the criteria required to be submitted to the server. If the application wishes to send the cookie, it can use the **SetCookie** method and specify the cookie name and value.

CHttpClient::GetData Method

```
INT GetData(  
    LPCTSTR lpszResource,  
    LPBYTE lpBuffer,  
    LPDWORD lpdwLength,  
    DWORD dwOptions  
);
```

```
INT GetData(  
    LPCTSTR lpszResource,  
    HGLOBAL *lpBuffer,  
    LPDWORD lpdwLength,  
    DWORD dwOptions  
);
```

```
INT GetData(  
    LPCTSTR lpszResource,  
    LPTSTR lpBuffer,  
    DWORD dwMaxLength  
);
```

```
INT GetData(  
    LPCTSTR lpszResource,  
    CString& strBuffer,  
    DWORD dwOptions  
);
```

The **GetData** method requests a resource from the server and copies the data to the specified buffer.

Parameters

lpszResource

A pointer to a string that specifies the resource that will be transferred to the local system. This may be the name of a file on the server, or it may specify the name of a script that will be executed and the output returned to the caller. This string may specify a valid URL for the current server that the client is connected to.

lpBuffer

A pointer to a byte buffer which will contain the data transferred from the server, or a pointer to a global memory handle which will reference the data when the method returns.

lpdwLength

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvBuffer* parameter. If the *lpvBuffer* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the number of bytes of data returned by the server.

dwMaxLength

An unsigned integer value which specifies the maximum number of characters can be copied into the *lpBuffer* string. This parameter is used with the version of the method that returns the data in a character array and includes the terminating null character. This value must be greater than one and the *lpBuffer* parameter cannot be NULL, otherwise the method will return an error.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a

bitwise operator with any of the following values:

Value	Description
HTTP_TRANSFER_DEFAULT	The default transfer mode. The resource data is downloaded to the local system exactly as it is stored on the server. If you are requesting a text-based resource, the data may use a different end-of-line character sequence. For example, the end-of-line character may be a single linefeed character instead of a carriage return and linefeed pair.
HTTP_TRANSFER_CONVERT	If the resource being downloaded from the server is textual, the data is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences.
HTTP_TRANSFER_COMPRESS	This option informs the server that the client is willing to accept compressed data. If the server supports compression for the specified resource, then the data will be automatically expanded before being returned to the caller. This option is selected by default if compression has been enabled using the EnableCompression method.
HTTP_TRANSFER_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the method to fail. Instead, the response is returned to the client and the method will succeed.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetData** method is used to retrieve a resource from the server and copy it into a local buffer. The method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the contents of the file. In this case, the *lpBuffer* parameter will point to the buffer that was allocated, the value that the *lpdwLength* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpBuffer* parameter point to a global memory handle which will contain the file data when the method returns. In this case, the value that the *lpdwLength* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

If the third method or fourth method is used, where the data is returned in a string buffer, the data may be modified so that the end-of-line character sequence matches the convention used by the Windows platform (a carriage return character followed by a linefeed). If Unicode is being used, the data will be converted from a byte array to a Unicode string. An application should only use these versions of the **GetData** method if the resource or remote file contains text.

It is important for your application to initialize the value of the *lpdwLength* parameter correctly. This parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when issuing the GET request to the server, the variable passed to this method may have a value of zero when the method returns, indicating no data has been returned to the caller.

When encountering a server error during a request, the **GetData** method normally returns HTTP_ERROR, and no data is copied into the caller-provided buffer. The last error code for the current thread is updated to reflect the general cause of the failure, allowing the application to handle this error condition appropriately. Additionally, servers may provide further details about the failure, such as XML or JSON formatted data containing specific error codes or diagnostic messages.

To capture this error information, you can utilize the HTTP_TRANSFER_ERRORDATA option. When this option is enabled, the behavior of **GetData** changes; it does not return HTTP_ERROR for server error statuses. Instead, any error data provided in the server's response, regardless of its format, is copied into the buffer provided by the caller.

If compression has been enabled and the server returns compressed data, it will be automatically expanded before being returned to the caller. This will result in a difference between the value returned in the *lpdwLength* parameter, which contains the actual number of bytes copied into the buffer, and the values reported by **GetTransferStatus**. For example, if the server returns 5,000 bytes of compressed data that expands into 15,000 bytes, this function will return 15,000 as the number of bytes copied into the buffer. However, the **GetTransferStatus** method will return the content length as the original 5,000 bytes of compressed data. For this reason, you should always use the value returned in the *lpdwLength* parameter to determine the amount of data that has been copied into the buffer.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hgblBuffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Return the file data into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hgblBuffer parameter
nResult = pClient->GetData(lpszResource, &hgblBuffer, &cbBuffer);

if (nResult != HTTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // resource data
    lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}
```

```
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

GetDefaultUserAgent Method

```
INT GetDefaultUserAgent(  
    LPTSTR lpszUserAgent,  
    INT nMaxLength  
);  
  
INT GetDefaultUserAgent(  
    CString& strUserAgent  
);
```

The **GetDefaultUserAgent** method returns the default user agent string which is included with all requests.

Parameters

lpszUserAgent

A pointer to a buffer which will contain the default user agent string when the method returns. The buffer must be large enough to contain the entire user agent string including the terminating null character. This parameter cannot be NULL. An alternate form of the method accepts a **CString** variable which will contain the user agent.

nMaxLength

An integer value which specifies the maximum number of characters which can be copied into the buffer.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **HttpGetLastError**.

Remarks

When you submit a request to the server, a header named **User-Agent** is automatically defined which identifies your application. It typically uses a format where you have a product name and version number separated by a slash. There can be multiple products listed in the user agent string, with additional optional information enclosed in parenthesis.

A server uses the user agent to determine what type of client has issued the request, including what operating system and browser version was used. The **HttpGetDefaultUserAgent** method returns a copy of that default value. The value of the user agent string depends on which version of Windows the client is running on and whether the process is 32-bit or 64-bit. For example, a 64-bit application will typically return a value like this:

```
Mozilla/5.0 (Windows NT 6.2; Win64; x64) Chrome/114.0.0.0 Safari/537.36  
SocketTools/11.0
```

Some web services check the value of the user agent string to determine if a compatible client is being used to issue the request. The default value is designed to emulate a common browser, but some services may require you change the user agent to use a specific value or include certain product names and versions.

You can change the value of the user agent string in one of two ways. You can use the **SetHeader** method to set the User-Agent header to a specific value for a client session, or you can use **SetDefaultUserAgent** to set the default user agent string for all requests. If you use **SetHeader** to change the user agent string for a client session, it will always override the default value.

To prevent any user agent string from being included with a request, include the HTTP_OPTION_NOUSERAGENT option when connecting to the server or use **SetOption** to enable that option after a connection has been established.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[GetDefaultUserAgent](#), [SetDefaultUserAgent](#), [SetOption](#), [SetHeader](#)

CHttpClient::GetEncodingType Method

INT GetEncodingType();

The **GetEncodingType** method determines which content-encoding option is enabled.

Parameters

None.

Return Value

If the method succeeds, the return value is one of the following values:

Value	Description
HTTP_ENCODING_NONE	No encoding will be applied to the content of a request and no default content type will be specified. This encoding type should be used with REST APIs and other services which expect XML or JSON request payloads.
HTTP_ENCODING_URL	Non-printable and extended ASCII characters will be encoded so they can be safely used with URLs and form data. Encoded characters will be represented by a percent symbol prefix, followed by a two digit hexadecimal value which represents the ASCII character code. This encoding is typically used with web services which process HTML form data.
HTTP_ENCODING_XML	This encoding is identical to URL encoding, except spaces are not encoded. It is used with legacy web services which expect form data in an XML format and cannot process encoded whitespace. This encoding should not be specified for services which use REST APIs.

If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The default encoding type is HTTP_ENCODING_URL which is used for submitting data to services which expect HTML form data using the **HttpPostData** or **HttpSubmitForm** functions.

When submitting a JSON or XML request to a service using a REST API, your application should use HTTP_ENCODING_NONE and set the appropriate content type for the request payload. The HTTP_ENCODING_XML encoding type should only be used if the server expects URL encoded form data. The **PostJson** and **PostXml** methods will automatically set the correct encoding and content type for those requests.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT cbDescription  
);  
  
INT GetErrorString(  
    DWORD dwErrorCode,  
    CString& strDescription  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length. An alternate form of the method accepts a **CString** variable which will contain the error description.

cbDescription

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is zero, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetFile Method

```
INT GetFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions  
);
```

The **GetFile** method downloads the specified file on the server to the local system.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be created, overwritten or appended to. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the resource on the server. This may be the name of a file on the server, or it may specify the name of a script that will be executed and the output returned to the caller. This string may specify a valid URL for the current server that the client is connected to.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_TRANSFER_DEFAULT	The default transfer mode. The resource data is downloaded to the local system exactly as it is stored on the server. If you are requesting a text-based resource, the data may use a different end-of-line character sequence. For example, the end-of-line character may be a single linefeed character instead of a carriage return and linefeed pair.
HTTP_TRANSFER_CONVERT	If the resource being downloaded from the server is textual, the data is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences.
HTTP_TRANSFER_COMPRESS	This option informs the server that the client is willing to accept compressed data. If the server supports compression for the specified resource, then the data will be automatically expanded before being returned to the caller. This option is selected by default if compression has been enabled using the EnableCompression method.
HTTP_TRANSFER_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the method to fail. Instead, the response is returned to the client and the method will succeed. If this option is used, your application should call HttpGetResultCode to obtain the

HTTP status code returned by the server. This will enable you to determine if the operation was successful.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Enabling compression does not guarantee that the data returned by the server will actually be compressed, it only informs the server that the client is willing to accept compressed data. Whether or not a particular resource is compressed depends on the server configuration, and the server may decide to only compress certain types of resources, such as text files. To determine if the server compressed the data returned to the client, use the **GetHeader** method to get the value of the **Content-Encoding** header after this function returns. If the header is defined, the value specifies the compression method used, otherwise the data was not compressed.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnableCompression](#), [EnableEvents](#), [GetData](#), [GetText](#), [GetTransferStatus](#), [PostData](#), [PutData](#), [PutFile](#), [RegisterEvent](#)

CHttpClient::GetFileSize Method

```
INT GetFileSize(  
    LPCTSTR lpszFileName,  
    LPDWORD lpFileSize  
);  
  
INT GetFileSize(  
    LPCTSTR lpszFileName,  
    ULARGE_INTEGER *lpFileSize  
);
```

The **GetFileSize** method returns the size of the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file.

lpdileSize

Points to an unsigned integer that will contain the size of the specified file in bytes. For files larger than 4GiB, this parameter should point to an unsigned 64-bit integer.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method uses the HEAD command to retrieve header information about the file without downloading the contents of the file itself. If the file does not exist or the client does not have permission to access the file, this method will fail and the *lpFileSize* parameter will be set to zero.

The server may not return a file size for some resources. This is typically the case with scripts that generate dynamic content because the server has no way of determining the size of the output generated by the script without actually executing it. The server may also not provide a file size for HTML documents which use server side includes (SSI) because that content is also dynamically created by the server. If the request to the server was successful and the file exists, but the server does not return a file size, the method will succeed but the file size returned to the caller will be zero.

When a request is made to the server for information about the file, the library will attempt to keep the connection alive, even if the HTTP_OPTION_KEEPALIVE option has not been specified for the session. This allows an application to request the file size and then download the file without having to write additional code to re-establish the connection. However, it is possible that the attempt to keep the connection open will fail. In that case, an error will be returned and the client handle will no longer be valid. If this happens, the *lpdwFileSize* parameter may still contain a valid value. If the library was able to determine the file size, but was not able to maintain the connection to the server, the returned file size will be greater than zero even if the method returns an error.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Command](#), [GetContentLength](#), [GetContentType](#), [GetFileTime](#), [VerifyFile](#)

CHttpClient::GetFileTime Method

```
INT GetFileTime(  
    LPCTSTR lpszFileName,  
    LPSYSTEMTIME lpFileTime,  
    BOOL bLocalize  
);
```

The **GetFileTime** method returns the modification time for the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file.

lpFileTime

Points to a [SYSTEMTIME](#) structure that will be set to the current modification time for the remote file.

bLocalize

A boolean flag which specifies if the file time is localized to the current timezone. If this value is non-zero, then the file time is adjusted to that the time is local to the current system. If this value is zero, the file time is returned in UTC time.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetFileTime** method can be used to determine the date and time that a file was last modified on the server. The time may either be localized to the current system, or it may be returned as UTC time.

This method uses the HEAD command to retrieve header information about the file without downloading the contents of the file itself. This requires that the server support at least version 1.0 of the protocol standard, or an error will be returned.

The server may not return a modification time for some resources. If the request to the server was successful and the file exists, but the server does not return a modification time, the method will succeed but all of the members of the SYSTEMTIME structure will be zero.

When a request is made to the server for information about the file, the library will attempt to keep the connection alive, even if the HTTP_OPTION_KEEPALIVE option has not been specified for the session. This allows an application to request the modification time and then download the file without having to write additional code to re-establish the connection. However, it is possible that the attempt to keep the connection open will fail. In that case, an error will be returned and the client handle will no longer be valid. If this happens, the SYSTEMTIME structure may still contain a valid value. If the library was able to determine the modification time, but was not able to maintain the connection to the server, the members of the SYSTEMTIME structure will specify a valid date and time.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

[Command](#), [GetFileSize](#)

CHttpClient::GetFirstCookie Method

```
BOOL GetFirstCookie(  
    LPTSTR lpszCookieName,  
    LPINT lpnNameLen,  
    LPTSTR lpszCookieValue,  
    LPINT lpnValueLen  
);  
  
BOOL GetFirstCookie(  
    CString& strCookieName,  
    CString& lpszCookieValue  
);
```

The **GetFirstCookie** method returns the first cookie set by the server.

Parameters

lpszCookieName

A pointer to a string buffer which will contain the name of the first cookie set by the server.

lpnNameLen

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the cookie name string.

lpszCookieValue

A pointer to a string buffer which will contain the name of the first cookie value set by the server. If the cookie value is not required, this parameter may be NULL.

lpnValueLen

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the cookie value string. If the *lpszCookieValue* parameter is NULL, this parameter should also be NULL.

Return Value

If the method succeeds, the return value is non-zero. If there are no cookies or the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **GetFirstCookie** method is used to enumerate the cookies set by the server after a resource has been requested. To get information about a specific cookie, use the **GetCookie** method.

Example

```
CString strCookieName;  
CString strCookieValue;  
BOOL bResult;  
  
// Get the first cookie set by the server  
bResult = pClient->GetFirstCookie(strCookieName, strCookieValue);  
  
while (bResult)  
{  
    // The strCookieName and strCookieValue strings contain the  
    // the name and value for a cookie set by the server
```

```
// Get the next cookie set by the server
bResult = pClient->GetNextCookie(strCookieName, strCookieValue);
};
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::GetFirstHeader Method

```
BOOL GetFirstHeader(  
    LPTSTR lpszHeader,  
    LPINT lpcchHeader  
    LPTSTR lpszValue,  
    LPINT lpcchValue  
);
```

```
BOOL GetFirstHeader(  
    CString& strHeader,  
    CString& strValue  
);
```

The **GetFirstHeader** method returns the name and value of the first response header.

Parameters

lpszHeader

A pointer to a string buffer that will contain the name of the header field when the method returns.

lpcchHeader

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the header name string.

lpszValue

A pointer to a string buffer that will contain the value of the header field when the method returns.

lpcchValue

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the header value string.

Return Value

If the method succeeds, the return value is non-zero. If the header field does not exist or the client handle is invalid, the method returns a value of zero. To get extended error information, call **GetLastError**.

Remarks

Use this method together with **GetNextHeader** to enumerate all request or response headers.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetFormProperties Method

```
INT GetFormProperties(  
    LPHTTPFORMPROPERTIES LpFormProp  
);
```

The **GetFormProperties** function returns information about the current form.

Parameters

lpFormProp

Points to a HTTPFORMPROPERTIES structure which will contain information about the current form.

Return Value

If the method succeeds, the return value is zero. If the function fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetHandle Method

```
HCLIENT GetHandle();
```

The **GetHandle** method returns the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to obtain the client handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `cshttpv11.lib`

See Also

[AttachHandle](#), [DetachHandle](#), [IsInitialized](#)

CHttpClient::GetHeader Method

```
BOOL GetHeader(  
    LPCTSTR lpszHeader,  
    LPTSTR lpszValue,  
    INT nMaxLength  
);
```

```
BOOL GetHeader(  
    LPCTSTR lpszHeader,  
    CString& strValue  
);
```

The **GetHeader** method returns the value of the specified response header field.

Parameters

lpszHeader

Pointer to a string which specifies the header value to be returned.

lpszValue

Pointer to a buffer which will contain the null-terminated string value of the specified header field. This may also be a **CString** object which will contain the value of the header field when the function returns.

nMaxLength

Maximum number of characters that may be copied into the buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is non-zero. If the header field does not exist or the client handle is invalid, the method returns a value of zero. To get extended error information, call **GetLastError**.

Remarks

When a resource is returned by the server, it consists of three parts. The first part consists of a single line that indicates the result of the request. The second part is one or more header fields which provides specific information about the resource, such as its size in bytes. The third part consists of the resource data itself, such as the HTML document or image data. For example, this is what the response to a request for a simple HTML document can look like:

```
HTTP/1.0 200 OK  
Date: Mon, 5 Jan 2004 20:18:33 GMT  
Content-Type: text/html  
Last-Modified: Mon, 5 Jan 2004 19:34:19 GMT  
Content-Length: 115
```

```
<html>  
<head>  
<title>Simple Document</title>  
</head>  
<body>  
This is a simple HTML document.  
</body>  
</html>
```

The first line consists of the protocol version, a numeric response code and some text describing the

result. The subsequent lines are the header, which is similar to the headers used in email messages. For example, the Date field specifies the date the resource was requested, the Content-Type field specifies what type of resource was requested, and the Content-Length field specifies the size of the resource in bytes. The end of the header block is indicated by an empty line (two carriage-return/linefeed sequences), and is followed by the resource itself, in this case a simple HTML document.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or HTTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[GetErrorString](#), [SetLastError](#), [ShowError](#)

CHttpClient::GetNextCookie

```
DWORD GetNextCookie(  
    LPTSTR lpszCookieName,  
    LPINT lpnNameLen,  
    LPTSTR lpszCookieValue,  
    LPINT lpnValueLen  
);
```

```
DWORD GetNextCookie(  
    CString& strCookieName,  
    CString& strCookieValue  
);
```

The **GetNextCookie** method returns the next cookie set by the server.

Parameters

lpszCookieName

A pointer to a string buffer which will contain the name of the first cookie set by the server.

lpnNameLen

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the cookie name string.

lpszCookieValue

A pointer to a string buffer which will contain the name of the first cookie value set by the server. If the cookie value is not required, this parameter may be NULL.

lpnValueLen

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the cookie value string. If the *lpszCookieValue* parameter is NULL, this parameter should also be NULL.

Return Value

If the method succeeds, the return value is non-zero. If there are no more cookies or the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **GetNextCookie** method is used to enumerate the cookies set by the server after a resource has been requested. To get information about a specific cookie, use the **GetCookie** method.

Example

```
CString strCookieName;  
CString strCookieValue;  
BOOL bResult;  
  
// Get the first cookie set by the server  
bResult = pClient->GetFirstCookie(strCookieName, strCookieValue);  
  
while (bResult)  
{  
    // The strCookieName and strCookieValue strings contain the  
    // the name and value for a cookie set by the server
```

```
// Get the next cookie set by the server
bResult = pClient->GetNextCookie(strCookieName, strCookieValue);
};
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[GetCookie](#), [GetFirstCookie](#), [GetHeader](#), [SetCookie](#), [SetHeader](#)

CHttpClient::GetNextHeader Method

```
BOOL GetNextHeader(  
    LPTSTR lpszHeader,  
    LPINT lpcchHeader,  
    LPTSTR lpszValue,  
    LPINT lpcchValue  
);
```

```
BOOL GetNextHeader(  
    CString& strHeader,  
    CString& strValue  
);
```

The **GetNextHeader** method returns the name and value of the next response header.

Parameters

lpszHeader

A pointer to a string buffer that will contain the name of the header field when the method returns.

lpcchHeader

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the header name string.

lpszValue

A pointer to a string buffer that will contain the value of the header field when the method returns.

lpcchValue

A pointer to an integer which specifies the maximum number of characters which may be copied into the buffer, including the terminating null character. When the method returns, this value is updated to specify the actual length of the header value string.

Return Value

If the method succeeds, the return value is non-zero. If the header field does not exist or the client handle is invalid, the method returns a value of zero. To get extended error information, call **GetLastError**.

Remarks

Use this method iteratively after **GetFirstHeader** to enumerate all request or response headers.

Unlike the **GetHeader** method, which returns a single header name and value, the **GetFirstHeader** and **GetNextHeader** methods will return multiple headers that have the same common name.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetOption Method

```
INT GetOption(  
    DWORD dwOption,  
    LPBOOL lpbEnabled  
);
```

The **GetOption** method determines whether a specified HTTP option is enabled.

Parameters

dwOption

An unsigned integer which specifies the option that is to be checked. It may be one of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_KEEPALIVE	This instructs the server to maintain a persistent connection between requests. This can improve performance because it eliminates the need to establish a separate connection for each resource that is requested.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_ERRORDATA	This option specifies the client should return the content of an error response from the server, rather than returning an error code. Note that this option will disable automatic resource redirection, and should not be used with HTTP_OPTION_REDIRECT.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server

	certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
HTTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
HTTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the handle is synchronized across multiple threads.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.

lpbEnabled

A pointer to an integer which will be set to a non-zero value when the method returns if the specified option has been enabled. If the option has not been enabled, a zero value will be returned in the variable.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**. Note that the value returned in the *lpbEnabled* parameter is only valid if the method succeeds.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::GetPriority Method

INT GetPriority();

The **GetPriority** method returns a value which specifies the priority of file transfers.

Parameters

None.

Return Value

If the method succeeds, the return value is the current file transfer priority. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetPriority** method can be used to determine the current priority assigned to file transfers performed by the client. It may be one of the following values:

Value	Description
HTTP_PRIORITY_NORMAL	The default priority which balances resource utilization and transfer speed. It is recommended that most applications use this priority.
HTTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the transfer. It is typically used with worker threads running in the background when the amount of time required perform the transfer is not critical.
HTTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the transfer and meters the bandwidth allocated for the transfer. This priority will increase the average amount of time required to complete a file transfer.
HTTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the transfer, allocating more memory for internal buffering. It can be used when it is important to transfer the file quickly, and there are no other threads currently performing file transfers at the time.
HTTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization while attempting to transfer the file as quickly as possible. If the file transfer is being performed in the main UI thread, this priority can cause the application to appear to become non-responsive. No events will be generated during the transfer.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::GetRedirectUrl Method

```
INT GetRedirectUrl(  
    LPTSTR lpszResource,  
    INT nMaxLength  
);  
  
INT GetRedirectUrl(  
    CString& strResource  
);
```

The **GetRedirectUrl** method returns the URL for a redirected resource.

Parameters

lpszResource

A pointer to a string buffer which will contain the URL of the redirected resource when the method returns. The string will be null terminated and the buffer must be large enough to accommodate the entire URL or the method will fail. This parameter cannot be a NULL pointer. An alternate form of the method accepts a **CString** variable which will contain the URL.

nMaxLength

The maximum number of characters that may be copied into the string buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the length of the URL. A return value of zero indicates that the request was not redirected. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method returns the complete URL for a request which has been redirected to a different resource. This is useful for applications which do not wish to use automatic redirection and instead prefer to handle the redirection by establishing a new connection by passing this value to the **ConnectUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::GetResourceUrl Method

```
INT GetResourceUrl(  
    LPTSTR lpszResource,  
    INT nMaxLength  
);  
  
INT GetResourceUrl(  
    CString& strResource  
);
```

The **GetResourceUrl** method returns the URL for the current request.

Parameters

lpszResource

A pointer to a string buffer which will contain the URL of the current resource when the method returns. The string will be null terminated and the the buffer must be large enough to accommodate the entire URL or the method will fail. This parameter cannot be a NULL pointer. An alternate form of the method accepts a **CString** variable which will contain the URL.

nMaxLength

The maximum number of characters that may be copied into the string buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the length of the URL. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method returns the URL for the current request which has been submitted to the server. This can be useful for applications which need to compose a URL for display or logging purposes, combining the connection information and resource path provided to methods such as **GetData** or **PostData**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ConnectUrl](#), [GetData](#), [GetRedirectUrl](#), [PostData](#)

CHttpClient::GetResultCode Method

```
INT GetResultCode();
```

The **GetResultCode** method reads the result code returned by the server in response to a command. The result code is a three-digit numeric code, and indicates if the operation succeeded, failed or requires additional action by the client.

Parameters

None.

Return Value

If the method succeeds, the return value is the result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Result codes are three-digit numeric values returned by the server. They may be broken down into the following ranges:

Value	Description
100-199	Positive preliminary result. This indicates that the requested action is being initiated, and the client should expect another reply from the server before proceeding.
200-299	Positive completion result. This indicates that the server has successfully completed the requested action.
300-399	Positive intermediate result. This indicates that the requested action cannot complete until additional information is provided to the server.
400-499	Transient negative completion result. This indicates that the requested action did not take place, but the error condition is temporary and may be attempted again.
500-599	Permanent negative completion result. This indicates that the requested action did not take place.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** cstdio11.h
- Import Library:** cshttpv11.lib

See Also

[Command](#), [GetResultString](#)

CHttpClient::GetResultString Method

```
INT GetResultString(  
    LPTSTR lpszResult,  
    INT cbResult  
);  
  
INT GetResultString(  
    CString& strResult  
);
```

The **GetResultString** method returns the last message sent by the server along with the result code.

Parameters

lpszResult

A pointer to the buffer that will contain the result string returned by the server. An alternate form of the method accepts a **CString** argument which will contain the result string returned by the server.

cbResult

The maximum number of characters that may be copied into the result string buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is the length of the result string. If a value of zero is returned, this means that no result string was sent by the server. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetResultString** method is most useful when an error occurs because the server will typically include a brief description of the cause of the error. This can then be parsed by the application or displayed to the user. The result string is updated each time the client sends a command to the server and then calls **GetResultCode** to obtain the result code for the operation.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[Command](#), [GetResultCode](#)

CHttpClient::GetSecurityInformation Method

```
BOOL GetSecurityInformation(  
    LPSECURITYINFO lpSecurityInfo  
);
```

The **GetSecurityInformation** method returns security protocol, encryption and certificate information about the current client connection.

Parameters

lpSecurityInfo

A pointer to a [SECURITYINFO](#) structure which contains information about the current client connection. The *dwSize* member of this structure must be initialized to the size of the structure before passing the address of the structure to this method.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method is used to obtain security related information about the current client connection to the server. It can be used to determine if a secure connection has been established, what security protocol was selected, and information about the server certificate. Note that a secure connection has not been established, the *dwProtocol* structure member will contain the value SECURITY_PROTOCOL_NONE.

Example

The following example notifies the user if the connection is secure or not:

```
SECURITYINFO securityInfo;  
securityInfo.dwSize = sizeof(SECURITYINFO);  
  
if (pClient->GetSecurityInformation(&securityInfo))  
{  
    if (securityInfo.dwProtocol == SECURITY_PROTOCOL_NONE)  
    {  
        MessageBox(NULL, _T("The connection is not secure"),  
                    _T("Connection"), MB_OK);  
    }  
    else  
    {  
        if (securityInfo.dwCertStatus == SECURITY_CERTIFICATE_VALID)  
        {  
            MessageBox(NULL, _T("The connection is secure"),  
                        _T("Connection"), MB_OK);  
        }  
        else  
        {  
            MessageBox(NULL, _T("The server certificate not valid"),  
                        _T("Connection"), MB_OK);  
        }  
    }  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetStatus Method

```
INT GetStatus();
```

The **GetStatus** method the current status of the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is the client status code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetStatus** method returns a numeric code which identifies the current state of the client session. The following values may be returned:

Value	Description
HTTP_STATUS_UNUSED	No connection has been established.
HTTP_STATUS_IDLE	The client is current idle and not sending or receiving data.
HTTP_STATUS_CONNECT	The client is establishing a connection with the server.
HTTP_STATUS_READ	The client is reading data from the server.
HTTP_STATUS_WRITE	The client is writing data to the server.
HTTP_STATUS_DISCONNECT	The client is disconnecting from the server.
HTTP_STATUS_GETDATA	The client is downloading data from the server.
HTTP_STATUS_PUTDATA	The client is uploading data to the server.
HTTP_STATUS_POSTDATA	The client is posting data to a script on the server.

In a multithreaded application, any thread in the current process may call this method to obtain status information for the specified client session. To obtain status information about a file transfer, use the **GetTransferStatus** method.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** cshttpv11.lib

CHttpClient::GetText Method

```
INT GetText(  
    LPCTSTR lpszResource,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);
```

The **GetText** method copies the contents of a text file on the server, or the text output from a script, to the specified string buffer.

Parameters

lpszResource

A pointer to a string that specifies the resource that will be transferred to the local system. This may be the name of a file on the server, or it may specify the name of a script that will be executed and the output returned to the caller. This string may specify a valid URL for the current server that the client is connected to.

lpszBuffer

A pointer to a string buffer which will contain the contents of the text file when the method returns. This buffer should be large enough to store the contents of the file, including a terminating null character. This parameter cannot be NULL.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. This value must be larger than zero. If this value is smaller than the actual size of the text file, the data returned will be truncated.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetText** method is used to download a text file or retrieve the text output from a script and store the contents in a string buffer. Because binary data can include embedded null characters which would truncate the string, this method should only be used with text files or script output that is known to be textual. For example, it is safe to use this method when a resource returns HTML or XML data, but should not be used if it returns an image or executable file.

This method has been included as a convenience for applications that need to retrieve relatively small amounts of textual data and manipulate the contents as a string. If the Unicode version of this method is called, the text is automatically converted to a Unicode string. If the maximum amount of data being returned is unknown or the amount of text is very large, it is recommended that you use the **GetData** or **GetFile** methods.

If you use the **GetFileSize** method to determine how large the string buffer should be prior to calling this method, it is important to be aware that the actual number of characters may differ based on the end-of-line conventions used by the host operating system. For example, if you call **GetFileSize** to obtain the size of a text file on a UNIX system, the value will not be large enough to store the complete file because UNIX uses a single linefeed (LF) character to indicate the end-of-line, while a Windows system will use a carriage-return and linefeed (CRLF) pair. To accommodate this difference, you should always allocate extra memory for the string buffer to store the additional end-of-line characters.

HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
LPTSTR lpszBuffer = (LPTSTR)calloc(MAXFILESIZE, sizeof(TCHAR));

if (lpszBuffer == NULL)
    return;

nResult = pHttpClient->GetText(lpszRemoteFile, lpszBuffer, MAXFILESIZE);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv10.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::GetTimeout Method

```
INT GetTimeout();
```

The **GetTimeout** method returns the number of seconds the client will wait for a response from the server. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

None.

Return Value

If the method succeeds, the return value is the timeout period in seconds. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections. A value of zero indicates that the default timeout period of 20 seconds should be used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[Connect](#), [IsReadable](#), [IsWritable](#), [Read](#), [SetTimeout](#), [Write](#)

CHttpClient::GetTransferStatus Method

```
INT GetTransferStatus(  
    LPHTTPTRANSFERSTATUS LpStatus  
);  
  
INT GetTransferStatus(  
    LPHTTPTRANSFERSTATUSEX LpStatus  
);
```

The **GetTransferStatus** method returns information about the current data transfer in progress.

Parameters

LpStatus

A pointer to an [HTTPTRANSFERSTATUS](#) or [HTTPTRANSFERSTATUSEX](#) structure which contains information about the status of the current data transfer.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetTransferStatus** method returns information about the current data transfer, including the average number of bytes transferred per second and the estimated amount of time until the transfer completes. If there is no data currently being transferred, this method will return the status of the last successful data transfer made by the client.

In a multithreaded application, any thread in the current process may call this method to obtain status information for the specified client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

CHttpClient::IsBlocking Method

BOOL IsBlocking();

The **IsBlocking** method is used to determine if the client is currently performing a blocking operation.

Parameters

None.

Return Value

If the client is performing a blocking operation, the method returns a non-zero value. If the client is not performing a blocking operation, or the client handle is invalid, the method returns zero.

Remarks

Because a blocking operation can allow the application to be re-entered (for example, by pressing a button while the operation is being performed), it is possible that another blocking method may be called while it is in progress. Since only one thread of execution may perform a blocking operation at any one time, an error would occur. The **IsBlocking** method can be used to determine if the client is already blocked, and if so, take some other action (such as warning the user that they must wait for the operation to complete).

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[Cancel](#), [GetStatus](#), [IsConnected](#), [IsInitialized](#), [IsReadable](#), [IsWritable](#), [Read](#), [Write](#)

CHttpClient::IsConnected Method

BOOL IsConnected();

The **IsConnected** method is used to determine if the client is currently connected to a server.

Parameters

None.

Return Value

If the client is connected to a server, the method returns a non-zero value. If the client is not connected, or the client handle is invalid, the method returns zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[GetStatus](#), [IsBlocking](#), [IsInitialized](#), [IsReadable](#), [IsWritable](#)

CHttpClient::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[CHttpClient](#), [IsBlocking](#), [IsConnected](#)

CHttpClient::IsReadable Method

```
BOOL IsReadable(  
    INT nTimeout,  
    LPDWORD LpdwAvail  
);
```

The **IsReadable** method is used to determine if data is available to be read from the server.

Parameters

nTimeout

Timeout for server response, in seconds. A value of zero specifies that the connection should be polled without blocking the current thread.

lpdwAvail

A pointer to an unsigned integer which will contain the number of bytes available to read. This parameter may be NULL if this information is not required.

Return Value

If the client can read data from the server within the specified timeout period, the method returns a non-zero value. If the client cannot read any data, the method returns zero.

Remarks

On some platforms, this value will not exceed the size of the receive buffer (typically 64K bytes). Because of differences between TCP/IP stack implementations, it is not recommended that your application exclusively depend on this value to determine the exact number of bytes available. Instead, it should be used as a general indicator that there is data available to be read.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[GetStatus](#), [IsBlocking](#), [IsConnected](#), [IsInitialized](#), [IsWritable](#), [Write](#)

CHttpClient::IsWritable Method

```
BOOL IsWritable(  
    INT nTimeout  
);
```

The **IsWritable** method is used to determine if data can be written to the server.

Parameters

nTimeout

Timeout for server response, in seconds. A value of zero specifies that the connection should be polled without blocking the current thread.

Return Value

If the client can write data to the server within the specified timeout period, the method returns a non-zero value. If the client cannot write any data, the method returns zero.

Remarks

Although this method can be used to determine if some amount of data can be sent to the remote process it does not indicate the amount of data that can be written without blocking the client. In most cases, it is recommended that large amounts of data be broken into smaller logical blocks, typically some multiple of 512 bytes in length.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

CHttpClient::OpenFile Method

```
INT OpenFile(  
    LPCTSTR lpszFileName  
);
```

The **OpenFile** method opens the specified file on the server.

Parameters

lpszFileName

Points to a string that specifies the name of the remote file to open.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Only one file may be opened at a time for each client session. Use the **CloseFile** method to close the file on the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::PatchData Method

```
INT PatchData(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszPatchData,  
    LPBYTE lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);  
  
INT PatchData(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszPatchData,  
    HGLOBAL *lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);  
  
INT PatchData(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszPatchData,  
    CString& strResult,  
    DWORD dwOptions  
);
```

The **PatchData** method submits patch data to the server and returns the result in a buffer provided by the caller.

Parameters

hClient

Handle to the client session.

lpszResource

A pointer to a string that specifies the resource name that the patch data will be submitted to. Typically this is the name of a script on the server.

lpszPatchData

A pointer to a string that specifies the patch data that will be submitted to the server.

lpvResult

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the method returns. An alternate version of this method accepts a **CString** object which will contain the server response.

lpcbResult

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvResult* parameter. If the *lpvResult* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the number of bytes of data returned by the server.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description

HTTP_PATCH_DEFAULT	The default patch mode. The contents of the buffer will be submitted without encoding. The data returned by the server is copied to the result buffer exactly as it is returned from the server.
HTTP_PATCH_CONVERT	If the data being returned from the server is textual, it is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences. Note that this option does not have any effect on the form data being submitted to the server, only on the data returned by the server.
HTTP_PATCH_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the function to fail. Instead, the response is returned to the client and the function will succeed.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PatchData** method is used to submit XML or JSON formatted patch data to a service, and then returns a copy of the response from the server into a local buffer. This method will not perform any encoding and will not automatically define the type of patch data being submitted. Your application is responsible for specifying the content type for the patch data, and ensuring that the XML or JSON data that is being submitted to the server is formatted correctly.

This method sends a PATCH command to the server, which is similar to a POST or PUT request. It is used to make partial updates to a resource, rather than creating or replacing it entirely. The format of the patch data is specific to the service being used. If the resource being patched does not exist, the behavior is defined by the server. If enough information is provided, it may choose to create the resource just as if a PUT command was used, or it may return an error.

Your application should use the **SetHeader** method to define the Content-Type header prior to calling the **PatchData** method. One of the most common formats used is the JSON Merge Patch which is defined in RFC 7396. The value for the Content-Type header for this patch format is "application/merge-patch+json". Refer to your service API documentation to determine what patch formats are acceptable, along with any additional header values that must be defined.

The method may be used in one of two ways, depending on the needs of the application. The first approach is to pre-allocate a buffer large enough to store the resulting output of the script. In this case, the **lpvResult** parameter will point to the buffer that was allocated by the client and the value that the **lpcbResult** parameter points to should be initialized to the size of that buffer.

The second approach is to have the **lpvResult** parameter point to a global memory handle which will contain the data when the method returns. In this case, the value that the **lpcbResult** parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

It is important for your application to initialize the value of the **lpcbResult** parameter correctly. This

parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when issuing the PATCH request to the server, the variable passed to this method may have a value of zero when the method returns, indicating no data has been returned to the caller.

When encountering a server error during a request, the **PatchData** method normally returns HTTP_ERROR, and no data is copied into the caller-provided buffer. The last error code for the current thread is updated to reflect the general cause of the failure, allowing the application to handle this error condition appropriately. If the PATCH request fails, servers may also provide further details about the failure, such as XML or JSON formatted data containing specific error codes or diagnostic messages.

To capture this error information, you can utilize the HTTP_PATCH_ERRORDATA option. When this option is enabled, the behavior of **PatchData** changes; it does not return HTTP_ERROR for server error statuses. Instead, any error data provided in the server's response, regardless of its format, is copied into the result buffer provided by the caller. If this option is used, your application should call **GetResultCode** to obtain the HTTP status code returned by the server. This will enable you to determine if the operation was successful.

This method will cause the current thread to block until the post completes, a timeout occurs or the operation is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of the transaction while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hglobalBuffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Store the script output into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hglobalBuffer parameter. Since the output from the
// script is textual, the HTTP_PATCH_CONVERT option is used

nResult = lpClient->PatchData(lpszResource,
                             lpszPatchData,
                             &hglobalBuffer,
                             &cbBuffer,
                             HTTP_PATCH_CONVERT);

if (nResult != HTTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // output data from the script
    lpBuffer = (LPBYTE)GlobalLock(hglobalBuffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hglobalBuffer);
    GlobalFree(hglobalBuffer);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::PostData Method

```
INT PostData(  
    LPCTSTR lpszResource,  
    LPBYTE lpBuffer,  
    DWORD cbBuffer,  
    LPBYTE lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);
```

```
INT PostData(  
    LPCTSTR lpszResource,  
    LPBYTE lpBuffer,  
    DWORD cbBuffer,  
    HGLOBAL *lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);
```

```
INT PostData(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszBuffer,  
    CString& strResult,  
    DWORD dwOptions  
);
```

The **PostData** method submits the contents of the specified buffer to a script on the server and returns the result in a buffer provided by the caller.

Parameters

lpszResource

A pointer to a string that specifies the resource that the data will be posted to on the server. Typically this is the name of an executable script. This string may specify a valid URL for the current server that the client is connected to.

lpBuffer

A pointer to the data that will be provided to the script. This parameter may be NULL if the script does not require any additional data from the client. In an alternate form of the method, this may point to a string which contains the data to be posted.

cbBuffer

The number of bytes to copy from the buffer. If the *lpBuffer* parameter is NULL, this value should be zero.

lpResult

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the method returns. An alternate version of this method accepts a **CString** object which will contain the server response.

lpcbResult

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvBuffer* parameter. If the *lpvResult* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the number of bytes of data returned by the server.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_POST_DEFAULT	The default post mode. The contents of the buffer are encoded and sent as standard form data. The data returned by the server is copied to the result buffer exactly as it is returned from the server.
HTTP_POST_CONVERT	If the data being returned from the server is textual, it is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences. Note that this option does not have any effect on the form data being submitted to the server, only on the data returned by the server.
HTTP_POST_MULTIPART	The contents of the buffer being sent to the server consists of multipart form data and will be sent as-is without any encoding.
HTTP_POST_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the method to fail. Instead, the response is returned to the client and the method will succeed.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PostData** method is used to submit data to a script that executes on the server and then copy the output from that script into a local buffer. If you are submitting XML formatted data to the server, it is recommended that you use the **PostXml** method to ensure that the correct content type and encoding is automatically selected.

The method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the resulting output of the script. In this case, the *lpvResult* parameter will point to the buffer that was allocated by the client and the value that the *lpcbResult* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpvResult* parameter point to a global memory handle which will contain the data when the method returns. In this case, the value that the *lpcbResult* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

It is important for your application to initialize the value of the *lpcbResult* parameter correctly. This parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when issuing the POST request to the server, the variable passed to this method may have a value of zero when the method returns, indicating no

data has been returned to the caller.

When encountering a server error during a request, the **PostData** method normally returns HTTP_ERROR, and no data is copied into the caller-provided buffer. The last error code for the current thread is updated to reflect the general cause of the failure, allowing the application to handle this error condition appropriately. If the POST request fails, servers may also provide further details about the failure, such as XML or JSON formatted data containing specific error codes or diagnostic messages.

To capture this error information, you can utilize the HTTP_POST_ERRORDATA option. When this option is enabled, the behavior of **PostData** changes; it does not return HTTP_ERROR for server error statuses. Instead, any error data provided in the server's response, regardless of its format, is copied into the result buffer provided by the caller. If this option is used, your application should call **GetResultCode** to obtain the HTTP status code returned by the server. This will enable you to determine if the operation was successful.

This method will cause the current thread to block until the post completes, a timeout occurs or the operation is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hgblBuffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Store the script output into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hgblBuffer parameter. Since the output from the
// script is textual, the HTTP_POST_CONVERT option is used

nResult = lpClient->PostData(lpszResource,
                             lpParameters,
                             cbParameters,
                             &hgblBuffer,
                             &cbBuffer,
                             HTTP_POST_CONVERT);

if (nResult != HTTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // output data from the script
    lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpClient::PostFile Method

```
INT PostFile(  
    LPCTSTR lpszFileName,  
    LPCTSTR lpszResource,  
    LPCTSTR lpszFieldName  
);
```

The **PostFile** method posts the contents of the specified file to a script executed on the server.

Parameters

lpszFileName

A pointer to a string that specifies the file that will be transferred from the local system. The file pathing and name conventions must be that of the local host.

lpszResource

A pointer to a string that specifies the resource on the server that the file data will be posted to. Typically this is the name of a script that is responsible for processing and storing the file data.

lpszFieldName

A pointer to a string that corresponds to the form field name that the script expects. If this parameter is NULL or an empty string, a default field name of "File1" is used.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PostFile** method is similar to the **PutFile** method in that it can be used to upload the contents of a local file to a server. However, instead of using the PUT command, the POST command is used to send the file data to a script that is executed on the server. This method has the advantage of not requiring any special configuration settings on the server, however it does require that the script be able to process multipart/form-data as defined in RFC 2388.

To support uploading files from a form on a webpage, the FILE input type is used along with the action that specifies the script that will accept the file data and process it. For example, the HTML code could look like this:

```
<form action="/cgi-bin/upload.cgi" method="post" enctype="multipart/form-data">  
<input type="file" name="datafile" size="20">  
<input type="submit">  
</form>
```

In this example, the script /cgi-bin/upload.cgi is responsible for processing the file data that is posted by the client, and the form field name "datafile" is used. The user can select a file, and when the Submit button is clicked, the file data is posted to the script. To simulate this using the **PostFile** method, the *lpszFileName* parameter should be set to the name of the local file that will be posted to the server. The *lpszResource* parameter should be the name of the script, in this case "/cgi-bin/upload.cgi". The *lpszFieldName* parameter should be specified as the string "datafile" to match the name of the field used by the form.

Note that the **PostFile** method always submits the file contents as multipart/form-data with the content type set to application/octet-stream. The script that accepts the posted data must be able to parse the multipart header block and correctly process 8-bit data. If the script assumes that the data

will be posted using a specific encoding type such as base64 then the file data may not be accepted or may be corrupted by the script.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

CHttpClient::PostJson Method

```
INT PostJson(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszJsonData,  
    LPBYTE lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);
```

```
INT PostJson(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszJsonData,  
    HGLOBAL *lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);
```

```
INT PostJson(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszJsonData,  
    CString& strResult,  
    DWORD dwOptions  
);
```

The **PostJson** method submits JSON formatted data to a script on the server and returns the result in a buffer provided by the caller.

Parameters

lpszResource

A pointer to a string that specifies the resource that the data will be posted to on the server. Typically this is the name of an executable script.

lpszJsonData

A pointer to a string that specifies the JSON data that will be submitted to the server.

lpResult

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the method returns. An alternate version of this method accepts a **CString** object which will contain the server response.

lpcbResult

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvResult* parameter. If the *lpvResult* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the number of bytes of data returned by the server.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_POST_DEFAULT	The default post mode. The contents of the buffer will be submitted without encoding and should use the standard JSON format. The data returned by the server is copied to the result

	buffer exactly as it is returned from the server.
HTTP_POST_CONVERT	If the data being returned from the server is textual, it is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences. Note that this option does not have any effect on the form data being submitted to the server, only on the data returned by the server.
HTTP_POST_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the method to fail. Instead, the response is returned to the client and the method will succeed.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PostJson** method is used to submit JSON formatted data to a script that executes on the server and then copy the output from that script into a local buffer. This function automatically sets the correct content type and encoding required for submitting JSON data to a server, however it does not parse the JSON data itself to ensure that it is well-formed. Your application is responsible for ensuring that the JSON data that is being submitted to the server is formatted correctly.

The method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the resulting output of the script. In this case, the *lpvResult* parameter will point to the buffer that was allocated by the client and the value that the *lpcbResult* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpvResult* parameter point to a global memory handle which will contain the data when the method returns. In this case, the value that the *lpcbResult* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

It is important for your application to initialize the value of the *lpcbResult* parameter correctly. This parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when issuing the POST request to the server, the variable passed to this method may have a value of zero when the method returns, indicating no data has been returned to the caller.

If the content type for the request has not been explicitly specified, it will be automatically updated by this function to use the "application/json" content type. You can override the default content type for the request by calling the **SetHeader** method prior to calling this method. Most servers require you to explicitly specify what type of data is being submitted by the client and will reject requests which do not correctly identify the content type.

When encountering a server error during a request, the **PostJson** method normally returns HTTP_ERROR, and no data is copied into the caller-provided buffer. The last error code for the current thread is updated to reflect the general cause of the failure, allowing the application to handle this error condition appropriately. If the POST request fails, servers may also provide further details about

the failure, such as XML or JSON formatted data containing specific error codes or diagnostic messages.

To capture this error information, you can utilize the `HTTP_POST_ERRORDATA` option. When this option is enabled, the behavior of **PostJson** changes; it does not return `HTTP_ERROR` for server error statuses. Instead, any error data provided in the server's response, regardless of its format, is copied into the result buffer provided by the caller. If this option is used, your application should call **GetResultCode** to obtain the HTTP status code returned by the server. This will enable you to determine if the operation was successful.

This method will cause the current thread to block until the post completes, a timeout occurs or the operation is canceled. During the transfer, the `HTTP_EVENT_PROGRESS` event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hgblBuffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Store the script output into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hgblBuffer parameter. Since the output from the
// script is textual, the HTTP_POST_CONVERT option is used
nResult = lpClient->PostJson(lpszResource,
                             lpszJsonData,
                             &hgblBuffer,
                             &cbBuffer,
                             HTTP_POST_CONVERT);

if (nResult != HTTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // output data from the script
    lpBuffer = (LPBYTE)GlobalLock(hgblBuffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hgblBuffer);
    GlobalFree(hgblBuffer);
}
```

CHttpClient::PostXml Method

```
INT PostXml(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszXmlData,  
    LPBYTE lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);  
  
INT PostXml(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszXmlData,  
    HGLOBAL *lpResult,  
    LPDWORD lpcbResult,  
    DWORD dwOptions  
);  
  
INT PostXml(  
    LPCTSTR lpszResource,  
    LPCTSTR lpszXmlData,  
    CString& strResult,  
    DWORD dwOptions  
);
```

The **PostXml** method submits XML formatted data to a script on the server and returns the result in a buffer provided by the caller.

Parameters

lpszResource

A pointer to a string that specifies the resource that the data will be posted to on the server. Typically this is the name of an executable script.

lpszXmlData

A pointer to a string that specifies the XML data that will be submitted to the server.

lpResult

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the method returns. An alternate version of this method accepts a **CString** object which will contain the server response.

lpcbResult

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvResult* parameter. If the *lpvResult* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the number of bytes of data returned by the server.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_POST_DEFAULT	The default post mode. The contents of the buffer will be submitted without encoding and should use the standard XML format. The data returned by the server is copied to the result

	buffer exactly as it is returned from the server.
HTTP_POST_CONVERT	If the data being returned from the server is textual, it is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences. Note that this option does not have any effect on the form data being submitted to the server, only on the data returned by the server.
HTTP_POST_ERRORDATA	This option causes the client to accept error data from the server if the request fails. If this option is specified, an error response from the server will not cause the method to fail. Instead, the response is returned to the client and the method will succeed.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PostXml** method is used to submit XML formatted data to a script that executes on the server and then copy the output from that script into a local buffer. This function automatically sets the correct content type and encoding required for submitting XML data to a server, however it does not parse the XML data itself to ensure that it is well-formed. Your application is responsible for ensuring that the XML data that is being submitted to the server is formatted correctly.

The method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the resulting output of the script. In this case, the *lpvResult* parameter will point to the buffer that was allocated by the client and the value that the *lpcbResult* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpvResult* parameter point to a global memory handle which will contain the data when the method returns. In this case, the value that the *lpcbResult* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the method must be freed by the application, otherwise a memory leak will occur. See the example code below.

It is important for your application to initialize the value of the *lpcbResult* parameter correctly. This parameter must be passed by reference and if it is not initialized properly it can cause unexpected behavior or corrupt the process heap. If an error occurs when issuing the POST request to the server, the variable passed to this method may have a value of zero when the method returns, indicating no data has been returned to the caller.

If the content type for the request has not been explicitly specified, it will be automatically updated by this function to use the "text/xml" content type. You can override the default content type for the request by calling the **SetHeader** method prior to calling this method. Most servers require you to explicitly specify what type of data is being submitted by the client and will reject requests which do not correctly identify the content type.

When encountering a server error during a request, the **PostXml** method normally returns HTTP_ERROR, and no data is copied into the caller-provided buffer. The last error code for the current thread is updated to reflect the general cause of the failure, allowing the application to handle this error condition appropriately. If the POST request fails, servers may also provide further details about

the failure, such as XML or JSON formatted data containing specific error codes or diagnostic messages.

To capture this error information, you can utilize the `HTTP_POST_ERRORDATA` option. When this option is enabled, the behavior of **PostXml** changes; it does not return `HTTP_ERROR` for server error statuses. Instead, any error data provided in the server's response, regardless of its format, is copied into the result buffer provided by the caller. If this option is used, your application should call **GetResultCode** to obtain the HTTP status code returned by the server. This will enable you to determine if the operation was successful.

This method will cause the current thread to block until the post completes, a timeout occurs or the operation is canceled. During the transfer, the `HTTP_EVENT_PROGRESS` event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Example

```
HGLOBAL hgb1Buffer = (HGLOBAL)NULL;
LPBYTE lpBuffer = (LPBYTE)NULL;
DWORD cbBuffer = 0;

// Store the script output into block of global memory allocated by
// the GlobalAlloc function; the handle to this memory will be
// returned in the hgb1Buffer parameter. Since the output from the
// script is textual, the HTTP_POST_CONVERT option is used

nResult = lpClient->PostXml(lpszResource,
                           lpszXmlData,
                           &hgb1Buffer,
                           &cbBuffer,
                           HTTP_POST_CONVERT);

if (nResult != HTTP_ERROR)
{
    // Lock the global memory handle, returning a pointer to the
    // output data from the script
    lpBuffer = (LPBYTE)GlobalLock(hgb1Buffer);

    // After the data has been used, the handle must be unlocked
    // and freed, otherwise a memory leak will occur
    GlobalUnlock(hgb1Buffer);
    GlobalFree(hgb1Buffer);
}
```

CHttpClient::ProxyConnect Method

```
BOOL ProxyConnect(
    UINT nProxyType,
    LPCTSTR lpszProxyHost,
    UINT nProxyPort,
    LPCTSTR lpszProxyUser,
    LPCTSTR lpszProxyPassword,
    LPCTSTR lpszRemoteHost,
    UINT nRemotePort,
    UINT nTimeout,
    DWORD dwOptions,
    DWORD dwVersion
);

BOOL ProxyConnect(
    LPCTSTR lpszRemoteHost,
    UINT nRemotePort,
    UINT nTimeout,
    DWORD dwOptions,
    DWORD dwVersion
);
```

The **ProxyConnect** method is used to establish a connection through a proxy server.

Parameters

nProxyType

An unsigned integer which specifies the type of proxy that the client is connecting to. The supported proxy server types are as follows:

Value	Description
HTTP_PROXY_NONE	A direct connection will be established with the server. When this value is specified the proxy parameters are ignored.
HTTP_PROXY_STANDARD	A standard connection is established through the specified proxy server, and all resource requests will be specified using a complete URL. This proxy type should be used with standard connections.
HTTP_PROXY_SECURE	A secure connection is established through the specified proxy server. This proxy type should be used with secure connections and the HTTP_OPTION_SECURE option should also be set via the <i>dwOptions</i> parameter.
HTTP_PROXY_WINDOWS	The configuration options for the current system should be used. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. These settings are the same proxy server settings configured in Windows.

lpszProxyHost

A pointer to a string which specifies the proxy server host name or IP address. This argument is ignored if the proxy type is set to HTTP_PROXY_NONE or HTTP_PROXY_WINDOWS and no proxy

configuration has been specified for the local system.

nProxyPort

The port number that the proxy server is listening for connections on. A value of zero specifies that the default port number 80 should be used. Note that in most cases, a proxy server is not configured to use the default port. This argument is ignored if the proxy type is set to HTTP_PROXY_NONE or HTTP_PROXY_WINDOWS and no proxy configuration has been specified for the local system.

lpszProxyUser

A pointer to a string which specifies the user name that will be used to authenticate the client session to the proxy server. If the server does not require user authentication, then a NULL pointer may be passed in this argument.

lpszProxyPassword

A pointer to a string which specifies the password that will be used to authenticate the client session to the proxy server. If the server does not require user authentication, then a NULL pointer may be passed in this argument.

lpszRemoteHost

A pointer to a string which specifies the name of the server to connect to through the proxy server. This may be a fully-qualified domain name or an IP address.

nRemotePort

The port number the server is listening on. A value of zero specifies that the default port number should be used. For standard connections, the default port number is 80. For secure connections, the default port number is 443.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_KEEPALIVE	This instructs the server to maintain a persistent connection between requests. This can improve performance because it eliminates the need to establish a separate connection for each resource that is requested.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.

HTTP_OPTION_ERRORDATA	This option specifies the client should return the content of an error response from the server, rather than returning an error code. Note that this option will disable automatic resource redirection, and should not be used with HTTP_OPTION_REDIRECT.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server. An application can provide its own custom user agent value using the SetHeader method.
HTTP_OPTION_HTTP2	This option specifies the client should attempt a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol. The value of the <i>dwVersion</i> parameter will be ignored when this option is used.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
HTTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
HTTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the handle is synchronized across multiple threads.

HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.
-------------------------	---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------

dwVersion

The requested protocol version used when sending requests to the server. The high word should specify the major version, and the low word should specify the minor version number. The HTTPVERSION macro can be used to create a version value and the following values are defined:

Value	Description
HTTP_VERSION_DEFAULT	The client should use the default protocol version for this session. This is the same as specifying HTTP_VERSION_11 and is recommended to ensure the broadest compatibility with most servers.
HTTP_VERSION_09	The client should use the original one-line protocol which includes no version number and no request header block. This version has been deprecated and should only be used with legacy servers which do not support the protocol standard. This version of the protocol does not support virtual hosts and is not supported by most modern web services.
HTTP_VERSION_10	The client should use the HTTP/1.0 protocol standard originally defined in RFC 1945. This version of the protocol supports the use of request header blocks, however it does not support persistent connections or chunked data and has limited cache control mechanisms.
HTTP_VERSION_11	The client should use the HTTP/1.1 protocol standard defined in RFC 2616 and RFC 7230. This is the most widely used version of the protocol and is the default for client connections. It is recommended most applications use this version.
HTTP_VERSION_20	The client should use the HTTP/2.0 protocol standard defined in RFC 7540. This protocol version is a significant change from previous versions and can provide improved performance with header compression and optimizing how requests are serviced.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **ProxyConnect** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

If the HTTP_PROXY_WINDOWS proxy type is specified, then the proxy configuration for the local system is used. If no proxy server has been defined, then the proxy-related parameters will be ignored

and the function will establish a connection directly to the server. The second form of the **ProxyConnect** method always uses the the system configuration to determine if the connection should be made through a proxy server, which is why there are no parameters such as the proxy type or proxy server name.

The *dwOptions* argument can be used to specify the threading model that is used by the library when a connection is established. By default, the handle is initially attached to the thread that created it. From that point on, until the it is released, only the owner may call functions using that handle. The ownership of the handle may be transferred from one thread to another using the **HttpAttachThread** function.

Specifying the HTTP_OPTION_FREETHREAD option enables any thread to call any function using the handle, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the library and may result in unexpected behavior unless access to the handle is synchronized. If one thread calls a function in the library, it must ensure that no other thread will call another function at the same time using the same handle.

If the HTTP_OPTION_KEEPALIVE option is specified and the server does not support persistent connections, the client will automatically reconnect when each resource is requested. Although it will not provide any performance benefits, this allows the option to be used with all servers. This option is automatically enabled when using HTTP/2.

Applications should use HTTP_VERSION_DEFAULT as the value for the *dwVersion* parameter. This will default to an appropriate version for the Windows platform and ensures the broadest compatibility with most servers. If your application specifies HTTP_VERSION_20, a secure connection using TLS 1.2 or later will always be used. The minimum required platform for HTTP/2 support is Windows 10 (Build 1903) or Windows Server 2019. Earlier versions of the Schannel SSP do not support the features required for a secure HTTP/2 connection.

If your application requests a HTTP/2 connection and the server only accepts earlier versions of the protocol, the client will attempt to automatically downgrade the request to HTTP/1.1. If a connection using an earlier version of the protocol cannot be established, the method will fail and return a value of zero.

Example

```
CHttpClient *pClient = new CHttpClient();

// Establish a connection using the default proxy server
// configuration for the local system

if (pClient->ProxyConnect(strHostName) == FALSE)
{
    pClient->ShowError();
    return;
}

// Retrieve the resource from the server and store it
// in the string buffer

nResult = pClient->GetData(strResource, strBuffer);

if (nResult == HTTP_ERROR)
    pClient->ShowError();

pClient->Disconnect();
delete pClient;
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Connect](#), [ConnectUrl](#), [Disconnect](#), [IsConnected](#)

CHttpClient::PutData Method

```
INT PutData(  
    LPCTSTR lpszRemoteFile,  
    LPBYTE lpBuffer,  
    DWORD dwLength  
);  
  
INT PutData(  
    LPCTSTR lpszRemoteFile,  
    LPCTSTR lpszBuffer  
);
```

The **PutData** method copies the contents of the specified buffer and stores it in a file on the server.

Parameters

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be created. This string may specify a valid URL for the current server that the client is connected to.

lpBuffer

A pointer to a buffer which will contain the data to be transferred from the client and stored in a file on the server. In an alternate form of the method, this may be a null terminated string.

dwLength

The number of bytes to copy from the buffer.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PutData** method is used to store the contents of the specified buffer in a file on the server. Not all servers permit files to be created using this method, and some may require that specific configuration changes be made to the server in order to support this functionality. Consult your server's technical reference documentation to see if it supports the PUT command, and if so, what must be done to enable it. It may be required that the client authenticate itself using the **Authenticate** method prior to uploading the data.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnableEvents](#), [GetData](#), [GetFile](#), [GetTransferStatus](#), [PostData](#), [PutFile](#), [RegisterEvent](#)

CHttpClient::PutFile Method

```
INT PutFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile  
);
```

The **PutFile** method transfers the specified file on the local system to the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the file that will be transferred from the local system. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the file on the server that will be created, overwritten or appended to. The file naming conventions must be that of the host operating system.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PutFile** method is used to transfer a file from the local system to a server. Not all servers permit files to be uploaded and some may require that specific configuration changes be made to the server in order to support this functionality. Consult your server's technical reference documentation to see if it supports the PUT command, and if so, what must be done to enable it. It may be required that the client authenticate itself using the **Authenticate** method prior to uploading the file.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnableEvents](#), [GetData](#), [GetFile](#), [GetTransferStatus](#), [PostData](#), [PostFile](#), [PutData](#), [RegisterEvent](#)

CHttpClient::PutText Method

```
INT PutText(  
    LPCTSTR lpszRemoteFile,  
    LPCTSTR lpszBuffer  
);
```

The **PutText** method creates a text file on the server using the contents of a string buffer.

Parameters

lpszRemoteFile

A pointer to a string that specifies the text file on the server that will be created or overwritten. This string may specify a valid URL for the current server that the client is connected to.

lpszBuffer

A pointer to a string that contains the text that will be stored in the file.

Return Value

If the method succeeds, the return value is the server result code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **PutText** method is used to create a text file on the server from the contents of a string. If the specified file already exists on the server, its contents will be overwritten. Not all servers permit files to be created using this method, and some may require that specific configuration changes be made to the server in order to support this functionality. Consult your server's technical reference documentation to see if it supports the PUT command, and if so, what must be done to enable it. It may be required that the client authenticate itself using the **Authenticate** method prior to uploading the data.

If the Unicode version of this method is called, the string will be converted to ASCII and then uploaded to the server. If you wish to store the contents of the string as Unicode on the server, you must use the **PutData** method. This method should never be used to upload binary data.

This method will cause the current thread to block until the file transfer completes, a timeout occurs or the transfer is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** method.

To determine the current status of a file transfer while it is in progress, use the **GetTransferStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv10.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpClient::Read Method

```
INT Read(  
    LPBYTE lpBuffer,  
    INT cbBuffer  
);  
  
INT Read(  
    CString& strBuffer,  
    INT cbBuffer  
);
```

The **Read** method reads the specified number of bytes from the client socket and copies them into the buffer. The data may be of any type, and is not terminated with a null character.

Parameters

lpBuffer

Pointer to the buffer in which the data will be copied. An alternate form of this method allows a **CString** variable to be passed and data read from the socket will be returned in that string.

cbBuffer

The maximum number of bytes to read and copy into the specified buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of bytes actually read. A return value of zero indicates that the server has closed the connection and there is no more data available to be read. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When **Read** is called and the client is in non-blocking mode, it is possible that the method will fail because there is no available data to read at that time. This should not be considered a fatal error. Instead, the application should simply wait to receive the next asynchronous notification that data is available.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

CHttpClient::RegisterEvent Method

```
INT RegisterEvent(  
    UINT nEventId,  
    HTTPEVENTPROC lpEventProc,  
    DWORD_PTR dwParam  
);
```

The **RegisterEvent** method registers an event handler for the specified event.

Parameters

nEventId

An unsigned integer which specifies which event should be registered with the specified callback function. One of the following values may be used:

Value	Description
HTTP_EVENT_CONNECT	The connection to the server has completed.
HTTP_EVENT_DISCONNECT	The server has closed the connection to the client. The client should read any remaining data and disconnect.
HTTP_EVENT_READ	Data is available to read by the calling process. No additional messages will be posted until the client has read at least some of the data. This event is only generated if the client is in asynchronous mode.
HTTP_EVENT_WRITE	The client can now write data. This notification is sent after a connection has been established, or after a previous attempt to write data has failed because it would result in a blocking operation. This event is only generated if the client is in asynchronous mode.
HTTP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
HTTP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.
HTTP_EVENT_COMMAND	A command has been issued by the client and the server response has been received and processed. This event can be used to log the result codes and messages returned by the server in response to actions taken by the client.
HTTP_EVENT_PROGRESS	The client is in the process of sending or receiving a file on the data channel. This event is called periodically during a transfer so that the client can update any user interface components such as a status control or progress bar.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **HttpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function. If the application targets the x86 (32-bit) platform, this parameter must be a 32-bit unsigned integer. If the application targets the x64 (64-bit) platform, this parameter must be a 64-bit unsigned integer.

Remarks

The **RegisterEvent** method associates a callback function with a specific event. The event handler is an **HttpEventProc** function that is invoked when the event occurs. Arguments are passed to the function to identify the client session, the event type and the user-defined value specified when the event handler is registered. If the event occurs because of an error condition, the error code will be provided to the handler.

This method is typically used to register an event handler that is invoked while a resource is being retrieved or data is being submitted to the server. The HTTP_EVENT_PROGRESS event will only be generated periodically during the transfer to ensure the application is not flooded with event notifications. It is guaranteed that at least one HTTP_EVENT_PROGRESS notification will occur at the beginning of the transfer, and one at the end of the transfer when it has completed.

The callback function specified by the *lpEventProc* parameter must be declared using the **__stdcall** calling convention. This ensures the arguments passed to the event handler are pushed on to the stack in the correct order. Failure to use the correct calling convention will corrupt the stack and cause the application to terminate abnormally.

The *dwParam* parameter is commonly used to identify the class instance which is associated with the event that has occurred. Applications will cast the **this** pointer to a DWORD_PTR value when calling this function, and then the event handler will cast it back to a pointer to the class instance. This gives the handler access to the class member variables and methods.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::SetBearerToken Method

```
INT SetBearerToken(  
    LPTSTR lpszBearerToken  
);
```

The **SetBearerToken** method sets the OAuth 2.0 bearer token used to authenticate the client session with a web service.

Parameters

lpszBearerToken

A pointer to a null terminated string buffer which contains the bearer token used to authorize client requests. If this parameter is NULL or a zero length string, the current bearer token will be cleared and no client authentication will be performed.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

Using OAuth 2.0 requires you to understand the process of how to request the bearer (access) token. Obtaining a bearer token requires registering your application with the web service provider, getting a unique client ID associated with your application and then requesting the token using the appropriate scope for the service. Obtaining the initial token will typically involve interactive confirmation on the part of the user, requiring they grant permission to your application to access the service.

Your application should not store a bearer token for later use. They have a relatively short lifespan, typically about an hour, and are designed to be used with that session. You should specify offline access as part of the OAuth 2.0 scope if necessary and store the refresh token provided by the service. The refresh token has a much longer validity period and can be used to obtain a new bearer token when needed.

Requirements

Minimum Desktop Platform: Windows 7 (Service Pack 1)

Minimum Server Platform: Windows Server 2008 R2 (Service Pack 1)

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Authenticate](#), [GetBearerToken](#), [SetHeader](#)

CHttpClient::SetCookie Method

```
BOOL SetCookie(  
    LPCTSTR lpszCookieName,  
    LPCTSTR lpszCookieValue  
);
```

The **SetCookie** method sends the specified cookie to the server when a resource is requested.

Parameters

lpszCookieName

Pointer to a string which specifies the name of the cookie that will be sent to the server when the next resource is requested.

lpszCookieValue

Pointer to a string which specifies the value of the cookie. To delete a cookie that has been previously set, this parameter should be NULL or point to an empty string.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **SetCookie** method submits the cookie name and value to the server when a resource is requested or data is posted to a script. For more information about cookies and how they are used, refer to the **GetCookie** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[ClearHeaders](#), [GetCookie](#), [GetFirstCookie](#), [GetNextCookie](#), [SetHeader](#)

CHttpClient::SetContentType Method

```
BOOL SetContentType(  
    LPCTSTR lpszContentType  
);
```

The **SetContentType** method sets the content type for the next request.

Parameters

hClient

Handle to the client session.

lpszContentType

A pointer to a null terminated string which contains the MIME content type of the data being submitted to the web server. If this parameter is NULL or an empty string, the current type will be cleared and the client will use a default type based on the request and content encoding.

Return Value

If the method succeeds, it will return a non-zero value. If the method fails, it will return zero. To get extended error information, call **HttpGetLastError**.

Remarks

The content type string must use the standard IANA format which consists of a type and subtype separated by a forward slash. Some common content types are:

Content Type	Description
text/plain	The request payload is unstructured text in a human readable format. This content type serves a default for textual data which does not explicitly have another standard subtype.
text/csv	The request payload is in a comma-separated value (CSV) text format.
application/octet-stream	The request payload contains binary data. This content type serves a default for binary data which does not explicitly have another standard subtype.
application/json	The request payload is standard JSON formatted text. This is the default content type used when submitting JSON requests, however some servers may expect the client to use the non-standard text/json type.
application/xml	The request payload is standard XML formatted text. This is the default content type used when submitting XML requests, however some servers may expect the client use the deprecated text/xml type. The standard content type for XML is defined in RFC 7303, however most servers will recognize both types as valid.

If a content type is not explicitly specified with a request, an appropriate default content type will be automatically selected. For example, the **PostJson** method will set the content type to **application/json** by default. This method can be used to override that default value.

This method will validate the content type, but does not validate the subtype. Unregistered subtypes should always be prefixed with "x-" which designates it as experimental. Some commonly used types also use this designation, such as **text/x-vcalendar** for the vCalendar format.

If your application needs to set the content type to a non-standard value for a proprietary API, use the **SetHeader** method to set the **Content-Type** header value. That method will not perform any validation on the header value and will include it in the request as-is.

The contents of the payload is not checked to ensure the content type is valid. It is the responsibility of the application to ensure that the correct content type is used when submitting the request.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[GetContentType](#), [GetHeader](#), [SetHeader](#)

CHttpClient::SetDefaultUserAgent Method

```
INT SetDefaultUserAgent(  
    LPCTSTR lpszUserAgent  
);
```

The **SetDefaultUserAgent** method sets the default user agent string which is included with all requests.

Parameters

lpszUserAgent

A pointer to a null terminated string which specifies the new default user agent string. If this parameter is NULL or an empty string, the client will revert to using the default user agent string defined when the library was first initialized.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **HttpGetLastError**.

Remarks

The **SetDefaultUserAgent** method changes the default user agent string which is included with each request made by the client. This default value is global and changing it will change the default user agent for all client sessions in all threads created by the process.

The user agent string should use a format with the product name and version number separated by a slash. There can be multiple products listed in the user agent string separated by spaces, with additional optional information enclosed in parenthesis. For example, a valid user agent string for an application named "MyProgram" could look like this:

MyProgram/1.0 (Win32)

Some web services check the value of the user agent string to determine if a compatible client is being used to issue the request. The default value used by SocketTools is designed to emulate a common browser, but some services may require you change the user agent to use a specific value or include certain product names and versions.

To change the user agent string for a specific client session, use the **SetHeader** method to set a value for the **User-Agent** header. To get the current value of the default user agent string, use the **GetDefaultUserAgent** method.

To prevent any user agent string from being included with a request, include the HTTP_OPTION_NOUSERAGENT option when connecting to the server or use **SetOption** to enable that option after a connection has been established.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetDefaultUserAgent](#), [SetOption](#), [SetHeader](#)

CHttpClient::SetEncodingType Method

```
INT SetEncodingType(  
    INT nEncodingType  
);
```

The **SetEncodingType** method specifies the type of encoding to be applied to the content of a HTTP request.

Parameters

nEncodingType

Specifies the content encoding type; currently-supported values are:

Value	Description
HTTP_ENCODING_NONE	No encoding will be applied to the content of a request and no default content type will be specified. This encoding type should be used with REST APIs and other services which expect XML or JSON request payloads.
HTTP_ENCODING_URL	Non-printable and extended ASCII characters will be encoded so they can be safely used with URLs and form data. Encoded characters will be represented by a percent symbol prefix, followed by a two digit hexadecimal value which represents the ASCII character code. This encoding is typically used with web services which process HTML form data.
HTTP_ENCODING_XML	This encoding is identical to URL encoding, except spaces are not encoded. It is used with legacy web services which expect form data in an XML format and cannot process encoded whitespace. This encoding should not be specified for services which use REST APIs.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SetEncodingType** method explicitly sets the type of encoding used when optional parameter data is submitted with a request for a resource. If an encoding type is specified, and the content type for the request payload has not been defined, it will default to **application/x-www-form-urlencoded**.

When submitting a JSON or XML request to a service using a REST API, your application should use HTTP_ENCODING_NONE and set the appropriate content type for the request payload. The HTTP_ENCODING_XML encoding type should only be used if the server expects URL encoded form data. The **PostJson** and **PostXml** methods will automatically set the correct encoding and content type for those requests.

If an application specifies HTTP_ENCODING_NONE, parameter data is not encoded and no content type header will be created by default. The client application can specify the content type by calling the **SetContentType** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpClient::SetFormProperties Method

```
INT SetFormProperties(  
    LPHTTPFORMPROPERTIES LpFormProp  
);
```

The **SetFormProperties** function updates the properties of the current form.

Parameters

LpFormProp

Points to a HTTPFORMPROPERTIES structure which specifies the new properties for the current form.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CreateForm](#), [GetFormProperties](#), [SubmitForm](#), [HTTPFORMPROPERTIES](#)

CHttpClient::SetHeader Method

```
BOOL SetHeader(  
    LPCTSTR lpszHeader,  
    LPCTSTR lpszValue  
);
```

The **SetHeader** method sets the value of the specified request header field.

Parameters

- lpszHeader*
Points to a string which specifies the request header field name.
- lpszValue*
Points to a string which specifies the value of the request header field.

Return Value

If the method succeeds, the return value is non-zero. If the client handle is invalid, the method returns a value of zero. To get extended error information, call **GetLastError**.

Remarks

The **SetHeader** method defines a header field and value that is submitted to the server when a resource is requested. If the header field has already been defined, it will be replaced by the new value. There are a number of header fields which are automatically created by the library, and others that are conditionally created depending on whether or not certain options are specified. The following header fields are automatically created by the library:

Header Field	Description
Accept	This header specifies the types of resources that are acceptable to the client. By default, all resource data types are accepted by the client.
Authorization	This header is automatically created if the client uses the Authenticate method to authenticate a client session.
Connection	This header determines if the connection is maintained after a resource has been requested, or if the connection should be immediately closed. The value of this header depends on whether the HTTP_OPTION_KEEPALIVE option has been specified.
Content-Length	This header defines the length of the data that is being posted to the server or the size of a file being uploaded to the server.
Content-Type	This header defines the content type for data posted to the server. This header is created if URL encoding is specified. The specific type of encoding used can be set by calling the SetEncodingType method.
Host	This header specifies the name of the server that the client has connected to. This is automatically generated when any resource is requested.
Pragma	This header is used to control caching performed by the server. If the option HTTP_OPTION_NOCACHE has been specified, this header will

	automatically be defined with the value "no-cache".
Proxy-Authorization	This header is automatically created if a proxy connection has been established and a username and password is required to authenticate the client session.

Request headers are generated by methods that send resource requests. In some cases, header values are supplied by the requesting method only if the application has not previously defined the header. For others, the requesting method overrides what the application may have defined.

If you use this method to set the Authorization header to a custom value for this client session, you must not call the **Authenticate** method. The **Authenticate** method will always override any custom Authorization header value and replace it with the credentials token generated from the username and password provided.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpClient::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the last error code for the current thread. This method is typically used to clear the last error by specifying a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the last error code for the current thread.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or HTTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by using the **GetLastError** method. The use of **GetLastError** is optional; an application can call the method to determine the specific reason for a method failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[GetErrorString](#), [GetLastError](#), [ShowError](#)

CHttpClient::SetOption Method

```
INT SetOption(  
    DWORD dwOption,  
    BOOL bEnabled  
);
```

The **SetOption** method enables or disables the specified option.

Parameters

hClient
Handle to the client session.

dwOption
An unsigned integer which specifies one of the following options:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_KEEPALIVE	This instructs the server to maintain a persistent connection between requests. This can improve performance because it eliminates the need to establish a separate connection for each resource that is requested. If the server does not support the keep-alive option, the client will automatically reconnect when each resource is requested. Although it will not provide any performance benefits, this allows the option to be used with all servers.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server.
HTTP_OPTION_ERRORDATA	This option specifies the client should return the content of an error response from the server, rather than returning an error code. Note that this option will disable automatic resource redirection, and should not be used with HTTP_OPTION_REDIRECT.
HTTP_OPTION_FREETHREAD	This option specifies the handle returned by this function may be used by any thread, and is not limited to the thread which created it. The application is responsible for

	ensuring that access to the handle is synchronized across multiple threads.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.

bEnabled

An integer value which determines if the option should be enabled or disabled. A non-zero value specifies that the option should be enabled, while a zero value specifies that the option should be disabled.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SetOption** method can only enable or disable the options listed above. Other options are only available when the connection is initially established. For example, you cannot use this function to enable security options or switch to using HTTP/2 after the connection has been made.

If you use HTTP_OPTION_FREETHREAD to permit any thread to reference a client handle allocated in another thread, your application is responsible for ensuring it does not attempt to submit requests using the same handle on different threads at the same time. If two different threads attempt to perform an operation using the same handle, there is no guarantee as to which thread will complete the operation first.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[Connect](#), [GetOption](#), [ProxyConnect](#)

CHttpClient::SetPriority Method

```
INT SetPriority(  
    INT nPriority  
);
```

The **SetPriority** method specifies the priority for file transfers.

Parameters

nPriority

An integer value which specifies the new priority for file transfers. It may be one of the following values:

Value	Description
HTTP_PRIORITY_NORMAL	The default priority which balances resource utilization and transfer speed. It is recommended that most applications use this priority.
HTTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the transfer. It is typically used with worker threads running in the background when the amount of time required perform the transfer is not critical.
HTTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the transfer and meters the bandwidth allocated for the transfer. This priority will increase the average amount of time required to complete a file transfer.
HTTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the transfer, allocating more memory for internal buffering. It can be used when it is important to transfer the file quickly, and there are no other threads currently performing file transfers at the time.
HTTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization while attempting to transfer the file as quickly as possible. If the file transfer is being performed in the main UI thread, this priority can cause the application to appear to become non-responsive. No events will be generated during the transfer.

Return Value

If the method succeeds, the return value is the previous file transfer priority. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SetPriority** method can be used to control the processor usage, memory and network bandwidth allocated for file transfers. The default priority balances resource utilization and transfer speed while ensuring that a single-threaded application remains responsive to the user. Lower priorities reduce the overall resource utilization at the expense of transfer speed. For example, if you create a worker thread to download a file in the background and want to ensure that it has a minimal impact on the

process, the HTTP_PRIORITY_BACKGROUND value can be used.

Higher priority values increase the memory allocated for the transfers and increases processor utilization for the transfer. The HTTP_PRIORITY_CRITICAL priority maximizes transfer speed at the expense of system resources. It is not recommended that you increase the file transfer priority unless you understand the implications of doing so and have thoroughly tested your application.

If the file transfer is being performed in the main UI thread, increasing the priority may interfere with the normal processing of Windows messages and cause the application to appear to become non-responsive. It is also important to note that when the priority is set to HTTP_PRIORITY_CRITICAL, normal progress events will not be generated during the transfer.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpClient::SetTimeout Method

```
INT SetTimeout(  
    UINT nTimeout  
);
```

The **SetTimeout** method sets the number of seconds the client will wait for a response from the server. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

nTimeout

The number of seconds to wait for a blocking operation to complete.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

CHttpClient::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** method in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that method for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpClient::SubmitForm Method

```
INT SubmitForm(
    LPBYTE lpResult,
    LPDWORD lpcbResult,
    DWORD dwOptions
);

INT SubmitForm(
    HGLOBAL *lpResult,
    LPDWORD lpcbResult,
    DWORD dwOptions
);

INT SubmitForm(
    CString& strResult,
    DWORD dwOptions
);
```

The **SubmitForm** method submits the contents of the current form to a script on the server and returns the result in a buffer provided by the caller.

Parameters

lpResult

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the function returns.

lpcbResult

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvBuffer* parameter. If the *lpvResult* parameter points to a global memory handle, the length value should be initialized to zero. When the function returns, this value will be updated with the actual number of bytes of data that was returned.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_SUBMIT_DEFAULT	The default post mode. The contents of the buffer are encoded and sent as standard form data. The data returned by the server is copied to the result buffer exactly as it is returned from the server.
HTTP_SUBMIT_CONVERT	If the data being returned from the server is textual, it is automatically converted so that the end of line character sequence is compatible with the Windows platform. Individual carriage return or linefeed characters are converted to carriage return/linefeed character sequences. Note that this option does not have any effect on the form data being submitted to the server, only on the data returned by the server.

Return Value

If the function succeeds, the return value is the server result code. If the function fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **SubmitForm** method is used to submit form data to a script that executes on the server and then copy the output from that script into a local buffer. The method may be used in one of two ways, depending on the needs of the application. The first method is to pre-allocate a buffer large enough to store the resulting output of the script. In this case, the *lpvResult* parameter will point to the buffer that was allocated by the client and the value that the *lpcbResult* parameter points to should be initialized to the size of that buffer.

The second method that can be used is have the *lpvResult* parameter point to a global memory handle which will contain the data when the function returns. In this case, the value that the *lpcbResult* parameter points to must be initialized to zero. It is important to note that the memory handle returned by the function must be freed by the application, otherwise a memory leak will occur. See the example code below.

This method will cause the current thread to block until the post completes, a timeout occurs or the operation is canceled. During the transfer, the HTTP_EVENT_PROGRESS event will be periodically fired, enabling the application to update any user interface controls. Event notification must be enabled, either by calling **EnableEvents**, or by registering a callback function using the **RegisterEvent** function.

To determine the current status of a transaction while it is in progress, use the **GetTransferStatus** function.

Example

```
CString strResult;  
INT nResult = 0;  
  
pClient->CreateForm(_T("/login.php"), HTTP_METHOD_POST, HTTP_FORM_ENCODED);  
pClient->AddField(_T("UserName"), lpszUserName);  
pClient->AddField(_T("Password"), lpszPassword);  
  
nResult = pClient->SubmitForm(strResult);  
pClient->DestroyForm();
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpClient::SubmitRequest Method

```
INT SubmitRequest(  
    DWORD dwRequestType,  
    LPCTSTR lpszResource,  
    LPHTTPCONNECTION lpConnection,  
    LPCVOID lpvRequest,  
    DWORD dwRequestLength,  
    LPVOID lpvResponse,  
    LPDWORD lpdwResponseLength  
);
```

The **SubmitRequest** method provides a high-level interface for submitting requests to a web service.

Parameters

dwRequestType

An unsigned integer which specifies the type of request being submitted to the server. It may be one of the following values:

Value	Description
HTTP_METHOD_DEFAULT	Perform a default request action based on the value of parameters passed to this method. If there is no request payload, the action will default to HTTP_METHOD_GET, otherwise it will default to HTTP_METHOD_POST. It is generally recommended that you explicitly specify the request method; however, this default value can be useful if your application does not know if a payload will be included with the request at the time the method is called.
HTTP_METHOD_GET	Use the GET method when submitting the request to the server. If this action is used, the <i>lpvRequest</i> and <i>dwRequestLength</i> parameters will be ignored. The buffer specified by the <i>lpvResponse</i> parameter will contain the server's response to the request.
HTTP_METHOD_POST	Use the POST method when submitting the request to the server. The payload specified by the <i>lpvRequest</i> parameter will be included with the request and the buffer specified by the <i>lpvResponse</i> parameter will contain the server's response to the request.
HTTP_METHOD_PUT	Use the PUT method when submitting the request to the server. The payload specified by the <i>lpvRequest</i> parameter will be included with the request. This method is typically used with persistent storage on the server, such as uploading the contents of a file. If the <i>lpvResponse</i> parameter is not NULL, it will contain any response from the server after the operation has completed.

lpszResource

A pointer to a null-terminated string which specifies the complete URL for the resource. Both standard and secure connections are supported, and query parameters may be included with the

URL. This parameter cannot be NULL and must specify an absolute (fully qualified) URI which begins with either http:// or https://.

lpConnection

A pointer to a **HTTPCONNECTION** structure which contains additional information about the client connection. This structure is required if your application must connect through a proxy server or when authentication is required to access a resource. This parameter can be NULL, in which case default values will be used when establishing the connection.

lpvRequest

A pointer to a buffer which contains the payload data submitted to the server as part of the request. This parameter may point to a byte buffer or a null-terminated string. If there is no payload required for the request this parameter may be NULL. If the Unicode version of this method is called and the request buffer contains text, it will be automatically converted to UTF-8 prior to submitting the data to the server. If the *dwRequestLength* parameter is -1, the payload will always be processed as a null-terminated string and the method will fail if the buffer does not contain text characters.

dwRequestLength

An unsigned integer which specifies the size of the request payload. If the payload contains text, this should specify the number of characters in the buffer. If the payload contains binary data, this value should specify the number of bytes in the buffer. If the *lpvRequest* parameter points to a null-terminated string, this value can be -1 and the length of the payload will be determined automatically. If the Unicode version of this method is called and the length is -1, the request payload will be UTF-8 encoded prior to being submitted to the server.

lpvResponse

A pointer to a byte buffer which will contain the data returned by the server, or a pointer to a global memory handle which will reference the data when the method returns. This parameter may be NULL if the response data is not required. If this parameter is NULL, the *lpdwResponseLength* parameter must also be NULL. If a response buffer is provided, the data will always be returned as a byte stream, even when the Unicode version of this method is called. If the server returns a text payload, it will typically be UTF-8 encoded and the application can convert the text to Unicode using the **MultiByteToWideChar** method.

lpdwResponseLength

A pointer to an unsigned integer which should be initialized to the maximum number of bytes that can be copied to the buffer specified by the *lpvResponse* parameter. If the *lpvResponse* parameter points to a global memory handle, the length value should be initialized to zero. When the method returns, this value will be updated with the actual number of bytes of data that was returned. If the *lpvResponse* parameter is not NULL, this parameter cannot be NULL.

Return Value

If the method succeeds, the return value is the server status code. If the method fails, the return value is HTTP_ERROR. To get extended error information, call the **GetLastError** method. The application should always check the return value to determine if the request was successful. If the server returns a 4xx or 5xx status code, this indicates the request was not accepted and the response buffer will typically contain information about the cause of the failure.

Remarks

The **SubmitRequest** method provides a single high-level interface for submitting requests to a web server and returning the server's response. This method is entirely self-contained and does not require a client session handle. The current thread will block until the method returns and will not generate

event notifications. If you need to download a large file from a web server and want progress updates, it is recommended you use the **DownloadFile** method.

If the service you are using requires authentication, you will need to allocate a **HTTPCONNECTION** structure and set the appropriate member values to specify the authentication method and user credentials. This structure also allows you to provide additional information, such as additional request header values, a custom timeout period and additional connection options.

When the *lpvRequest* parameter is not NULL, the contents of the buffer will be examined to determine if it contains text or binary data. If the *dwRequestLength* parameter is -1, the *lpvRequest* parameter is always considered to be a pointer to a null-terminated string, with the length calculated by counting the number of characters up to the terminating null character. If the request payload is text, the method will also attempt to determine if the payload looks like XML or JSON and will automatically set the appropriate content type. The application can explicitly provide a MIME content type by setting the *lpzContentType* member of the **HTTPCONNECTION** structure.

Example

```
// Submit an XML payload to the server and return the response in a global
// memory buffer allocated by the method
LPCTSTR lpszResource = _T("https://www.example.com/postxml");
LPCTSTR lpszRequest = _T("<?xml version='1.0' encoding='utf-8'>\r\n") \
    _T("<test>\r\n") \
    _T("  <data param='A'>Value1</data>\r\n") \
    _T("  <data param='B'>Value2</data>\r\n") \
    _T("</test>\r\n");

// Provide additional connection information which includes user credentials
// and a custom header which includes an API token for the service; note that
// we need to initialize the dwSize member of the structure
HTTPCONNECTION httpConnection = { 0, };
httpConnection.dwSize = sizeof(httpConnection);
httpConnection.nAuthType = HTTP_AUTH_BASIC;
httpConnection.lpszUserName = _T("userid");
httpConnection.lpszPassword = _T("secret");
httpConnection.lpszContentType = _T("application/xml");
httpConnection.lpszHeaders = _T("X-API-Token: 99d2fe39-0246-4efa-98e0-
4d775579fa5d");

// Declare the global memory handle which will contain the server response
// and initialize the length to 0, which tells the API that a HGLOBAL handle
// is being used rather than a pointer to a pre-allocated buffer
CHttpClient httpClient;
HGLOBAL hgb1Response = NULL;
DWORD dwLength = 0;

INT nResult = httpClient.SubmitRequest(
    HTTP_METHOD_POST,
    lpszResource,
    &httpConnection,
    lpszRequest,
    (DWORD)-1,
    &hgb1Response,
    &dwLength);

if (nResult != HTTP_ERROR && hgb1Response != NULL)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgb1Response);
```

```
// The lpBuffer variable points to the data returned by the server and  
// the application is responsible for freeing the global memory handle
```

```
GlobalUnlock(hgblResponse);  
GlobalFree(hgblResponse);  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DownloadFile](#), [GetData](#), [PostData](#), [PostJson](#), [PostXml](#), [UploadFile](#), [HTTPCONNECTION](#)

CHttpClient::UploadFile Method

```
BOOL UploadFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    UINT nTimeout  
    DWORD dwOptions  
    LPHTTPTRANSFERSTATUS lpStatus  
    HTTPEVENTPROC lpEventProc  
    DWORD_PTR dwParam  
);
```

The **UploadFile** method uploads the specified file from the local system to the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the file on the local system that will be uploaded to the server. The file pathing and name conventions must be that of the local host.

lpszRemoteFile

A pointer to a string that specifies the complete URL of the file that will be created or overwritten on the server. The URL must follow the conventions for the File Transfer Protocol and may specify either a standard or secure connection, alternate port number, username, password and optional working directory.

nTimeout

The number of seconds that the client will wait for a response before failing the operation. A value of zero specifies that the default timeout period of sixty seconds will be used.

dwOptions

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_OPTION_NOCACHE	This instructs the server to not return a cached copy of the resource. When connected to an HTTP 1.0 or earlier server, this directive may be ignored.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_PROXY	This option specifies the client should use the default proxy configuration for the local system. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. The local proxy configuration can be changed using the system Control Panel.

HTTP_OPTION_NOUSERAGENT	This option specifies the client should not include a User-Agent header with any requests made during the session. The user agent is a string which is used to identify the client application to the server. If this option is not specified, a default user agent string will be included with the request.
HTTP_OPTION_HTTP2	This option specifies the client should attempt a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol.
HTTP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
HTTP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.
HTTP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
HTTP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
HTTP_OPTION_HIRES_TIMER	This option specifies the elapsed time for data transfers should be returned in milliseconds instead of seconds. This will return more accurate transfer times for smaller amounts of data over fast network connections.

lpStatus

A pointer to an HTTPTRANSFERSTATUS structure which contains information about the status of the current file transfer. If this information is not required, a NULL pointer may be specified as the parameter.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **HttpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **UploadFile** method provides a convenient way for an application to upload a file in a single function call. Based on the connection information specified in the URL, it will connect to the server, authenticate the session and then upload the file to the server. The URL must be complete, and specify either a standard or secure HTTP scheme:

```
[http|https]://[username : password] @[hostname [:port] / [path / ...]  
[filename]
```

If no user name and password is provided, then the client session will be authenticated as an anonymous user. If a path is specified as part of the URL, then function will attempt to change the current working directory. Note that the path in an HTTP URL is relative to the home directory of the user account and is not an absolute path starting at the root directory on the server. The URL scheme will always determine if the connection is secure, not the option. In other words, if the "http" scheme is used and the HTTP_OPTION_SECURE option is specified, that option will be ignored. To establish a secure connection, the "https" scheme must be specified.

Not all web servers permit files to be uploaded and some may require that specific configuration changes be made to the server in order to support this functionality. Consult your server's technical reference documentation to see if it supports the PUT command, and if so, what must be done to enable it. It may be required that the URL specify a username and password to upload a file.

If your application requests a HTTP/2 connection and the server only accepts earlier versions of the protocol, the client will attempt to automatically downgrade the request to HTTP/1.1. If a connection using an earlier version of the protocol cannot be established, the method will fail and return a value of zero.

The *lpStatus* parameter can be used by the application to determine the final status of the transfer, including the total number of bytes copied, the amount of time elapsed and other information related to the transfer process. If this information isn't needed, then this parameter may be specified as NULL.

The *lpEventProc* parameter specifies a pointer to a function which will be periodically called during the file transfer process. This can be used to check the status of the transfer by calling **GetTransferStatus** and then update the program's user interface. For example, the callback function could calculate the percentage for how much of the file has been transferred and then update a progress bar control. The *dwParam* parameter is used in conjunction with the event handler and specifies a user-defined value that is passed to the callback function. One common use in a C++ program is to pass the *this* pointer as the value, and then cast it back to an object pointer inside the callback function. If no event handler

is required, then a NULL pointer can be specified as the value for *lpEventProc* and the *dwParam* parameter will be ignored.

The **UploadFile** method is designed to provide a simpler interface for uploading a file. However, complex connections such as those using a proxy server or a secure connection which uses a client certificate will require the program to establish the connection using **Connect** and then use **PutFile** to upload the file. If the server does not support the PUT command, you may be able to upload files using the **PostFile** method. Refer to that method for more information.

Example

```
CHttpClient httpClient;  
CString strLocalFile = _T("c:\\temp\\database.mdb");  
CString strFileURL =  
_T("http://update:secret@www.example.com/updates/database.mdb");  
  
if (!httpClient.UploadFile(strLocalFile, strFileURL))  
{  
    httpClient.ShowError();  
    return;  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DownloadFile](#), [GetTransferStatus](#), [HttpEventProc](#), [PostFile](#), [PutFile](#), [HTTPTRANSFERSTATUS](#)

CHttpClient::ValidateHostName Method

```
BOOL ValidateHostName(  
    LPCTSTR lpszHostName,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);
```

```
BOOL ValidateHostName(  
    LPCTSTR lpszHostName,  
    CString& strAddress  
);
```

The **ValidateHostName** method determines if the specified host name is valid and returns its IP address.

Parameters

lpszHostName

A pointer to a null terminated string which specifies the host name. The method will fail if this parameter is NULL or an empty string.

lpszAddress

A pointer to a string buffer which will contain the IP address of the host. If specified, this string must be large enough to store the complete IP address, including the terminating null character. If this parameter is NULL or the *nMaxLength* parameter is zero, it will be ignored and the IP address will not be returned. An alternate version of this method accepts a reference to a **CString** object if MFC or ATL is used with the project.

nMaxLength

An integer value that specifies the maximum number of characters which can be copied into the *lpszAddress* string buffer. The buffer must be large enough to store the complete address. Because this method can return either an IPv4 or IPv6 address, it is recommended the minimum length for the buffer to be 46 characters. If this parameter is zero, the *lpszAddress* parameter will be ignored.

Return Value

If the method succeeds, the host name is valid and the return value will be non-zero. If the method fails, the host name could not be resolved to an IP address and the return value will be zero. To get extended error information, call the **GetLastError** method.

Remarks

The **ValidateHostName** method provides a convenient way to determine if a host name is valid by attempting to resolve the name into an IP address. If the Unicode version of this method is used, any non-ASCII characters in the host name will be automatically encoded into a compatible format and then resolved to an IP address. If you are unsure if an internationalized domain name will be specified as the host name, it is recommended you use the Unicode version.

If the *lpszHostName* parameter specifies a valid IPv4 or IPv6 address string instead of a host name, this method will return a copy of that IP address in the buffer provided by the caller. This allows the method to be used in cases where a user may input either a host name or IP address.

If you wish to validate a complete HTTP URL instead of a host name, use the **ValidateUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ConnectUrl](#), [ValidateUrl](#)

CHttpClient::ValidateUrl Method

```
BOOL CHttpClient::ValidateUrl(  
    LPCTSTR lpszUrl  
);
```

The **ValidateUrl** method determines if a string represents a valid HTTP URL.

Parameters

lpszUrl

A pointer to a string that specifies the URL to validate.

Return Value

If the specified URL is valid and the host name can be resolved to an IP address, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **HttpGetLastError**.

Remarks

The **ValidateUrl** method will check the value of a string to ensure that it represents a complete, valid URL using either a standard or secure HTTP scheme. This method will not establish a connection with the server to verify that it exists, it will only attempt to resolve the host name to an IP address. If the remote host is specified as an IP address, this method will check to make sure that the address is formatted correctly. Note that if you wish to specify an IPv6 address, you must enclose the address in brackets.

To establish a connection with a server using a URL, use the **ConnectUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpClient::VerifyFile Method

```
BOOL VerifyFile(  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile  
);
```

The **VerifyFile** method attempts to verify that the size of a file on the local system is the same as the specified file on the server.

Parameters

lpszLocalFile

A pointer to a string that specifies the name of file on the local system.

lpszRemoteFile

A pointer to a string that specifies the name of the file on the server.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **VerifyFile** method will attempt to verify that the contents of the local and remote files are identical by comparing the size of the files. This method is provided for compatibility with the File Transfer Protocol API, and should not be considered a reliable method for comparing files. Web servers may not consistently return file size information for dynamically created content such as HTML pages which use server-side includes.

It is not recommended that you use this method with text files because of the different end-of-line conventions used by different operating systems. For example, a text file on a Windows system uses a carriage-return and linefeed pair to indicate the end of a line of text. However, on a UNIX system, a single linefeed is used to indicate the end of a line. This can cause the **VerifyFile** method to indicate the files are not identical, even though the only difference is in the end-of-line characters that are used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DeleteFile](#), [GetFile](#), [GetFileSize](#), [PutFile](#)

CHttpClient::Write Method

```
INT Write(  
    LPBYTE lpBuffer,  
    INT cbBuffer  
);  
  
INT Write(  
    LPCTSTR lpszBuffer  
    INT cbBuffer  
);
```

The **Write** method sends the specified number of bytes to the server.

Parameters

lpBuffer

The pointer to the buffer which contains the data that is to be sent to the server. In an alternate form of the method, the pointer is to a string.

cbBuffer

The number of bytes to send from the specified buffer. This value must be greater than zero, unless a pointer to a null-terminated string is passed as the buffer argument. In that case, if the value is -1, all of the characters in the string, up to but not including the terminating null character, will be sent to the server.

Return Value

If the method succeeds, the return value is the number of bytes actually written. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The return value may be less than the number of bytes specified by the *cbBuffer* parameter. In this case, the data has been partially written and it is the responsibility of the client application to send the remaining data at some later point. For non-blocking clients, the client must wait for the next asynchronous notification message before it resumes sending data.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

HTTPFORMPROPERTIES

This structure is used by the **GetFormProperties** and **SetFormProperties** methods to return and modify the properties of the specified form.

```
typedef struct _HTTPFORMPROPERTIES
{
    UINT      nFormMethod;
    UINT      nFormType;
    LPCTSTR   lpszFormAction;
    DWORD     dwReserved1;
    DWORD     dwReserved2;
} HTTPFORMPROPERTIES, *LPHTTPFORMPROPERTIES;
```

Members

nFormMethod

An unsigned integer value which specifies how the form data will be submitted to the server. It may be one of the following values:

Value	Description
HTTP_METHOD_GET	The form data should be submitted using the GET command. This method should be used when the amount of form data is relatively small. If the total amount of form data exceeds 2048 bytes, it is recommended that the POST method be used instead.
HTTP_METHOD_POST	The form data should be submitted using the POST command. This is the preferred method of submitting larger amounts of form data. If the total amount of form data exceeds 2048 bytes, it is recommended that the POST method be used.

nFormType

An unsigned integer value which specifies the type of form and how the data will be encoded when it is submitted to the server. It may be one of the following values:

Value	Description
HTTP_FORM_ENCODED	The form data should be submitted as URL encoded values. This is typically used when the GET method is used to submit the data to the server.
HTTP_FORM_MULTIPART	The form data should be submitted as multipart form data. This is typically used when the POST method is used to submit a file to the server. Note that the script must understand how to process multipart form data if this form type is specified.

lpszFormAction

A pointer to a string which specifies the name of the resource that the form data will be submitted to. Typically this is the name of a script that is executed on the server.

dwReserved1

A reserved structure member.

dwReserved2

A reserved structure member.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

HTTPTRANSFERSTATUS

This structure is used by the **GetTransferStatus** method to return information about a data transfer in progress.

```
typedef struct _HTTPTRANSFERSTATUS
{
    DWORD    dwBytesTotal;
    DWORD    dwBytesCopied;
    DWORD    dwBytesPerSecond;
    DWORD    dwTimeElapsed;
    DWORD    dwTimeEstimated;
} HTTPTRANSFERSTATUS, *LPHTTPTRANSFERSTATUS;
```

Members

dwBytesTotal

The total number of bytes that will be transferred. If the data is being downloaded from the server to the local host, this is the size of the requested resource. If the data is being uploaded from the local host to the server, it is the size of the local file or memory buffer. If the size of the resource cannot be determined, this value will be zero.

dwBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the data transfer is completed. This is based on the average number of bytes transferred per second.

Remarks

If the option HTTP_OPTION_HIRES_TIMER has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small amounts of data over a fast network connection.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

HTTPTRANSFERSTATUSEX

This structure is used by the **GetTransferStatus** method to return information about a data transfer in progress. This structure is designed for use with extended functions that support files larger than 4GB.

```
typedef struct _HTTPTRANSFERSTATUSEX
{
    ULARGE_INTEGER uiBytesTotal;
    ULARGE_INTEGER uiBytesCopied;
    DWORD          dwBytesPerSecond;
    DWORD          dwTimeElapsed;
    DWORD          dwTimeEstimated;
} HTTPTRANSFERSTATUSEX, *LPHTTPTRANSFERSTATUSEX;
```

Members

uiBytesTotal

The total number of bytes that will be transferred. If the data is being downloaded from the server to the local host, this is the size of the requested resource. If the data is being uploaded from the local host to the server, it is the size of the local file or memory buffer. If the size of the resource cannot be determined, this value will be zero.

uiBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the data transfer is completed. This is based on the average number of bytes transferred per second.

Remarks

If the option HTTP_OPTION_HIRES_TIMER has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small amounts of data over a fast network connection.

SECURITYCREDENTIALS

The **SECURITYCREDENTIALS** structure specifies the information needed by the library to specify additional security credentials, such as a client certificate, when establishing a secure connection.

```
typedef struct _SECURITYCREDENTIALS
{
    DWORD    dwSize;
    DWORD    dwProtocol;
    DWORD    dwOptions;
    DWORD    dwReserved;
    LPCTSTR  lpszHostName;
    LPCTSTR  lpszUserName;
    LPCTSTR  lpszPassword;
    LPCTSTR  lpszCertStore;
    LPCTSTR  lpszCertName;
    LPCTSTR  lpszKeyFile;
} SECURITYCREDENTIALS, *LPSECURITYCREDENTIALS;
```

Members

- dwSize***
Size of this structure. If the structure is being allocated dynamically, this member must be set to the size of the structure and all other unused structure members must be initialized to a value of zero or NULL.
- dwProtocol***
A bitmask of supported security protocols. The value of this structure member is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing

	a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

dwOptions

A value which specifies one or options. This member is constructed by using a bitwise operator with any of the following values:

Value	Description
CREDENTIAL_STORE_CURRENT_USER	The library will attempt to open a store for the current user using the certificate store name provided in this structure. If no options are specified, then this is the default behavior.
CREDENTIAL_STORE_LOCAL_MACHINE	The library will attempt to open a local machine store using the certificate store name provided in this structure. If this option is specified, the library will always search for a local machine store before searching for the store by that name for the current user.
CREDENTIAL_STORE_FILENAME	The certificate store name is a file that contains the certificate and private key that will be used.

dwReserved

This structure member is reserved for future use and should always be initialized to zero.

lpszHostName

A pointer to a null terminated string which specifies the hostname that will be used when validating the server certificate. If this member is NULL, then the server certificate will be validated against the hostname used to establish the connection.

lpszUserName

A pointer to a null terminated string which identifies the owner of client certificate. Currently this member is not used by the library and should always be initialized as a NULL pointer.

lpszPassword

A pointer to a null terminated string which specifies the password needed to access the certificate. Currently this member is only used if the CREDENTIAL_STORE_FILENAME option has been specified. If there is no password associated with the certificate, then this member should be initialized as a NULL pointer.

lpszCertStore

A pointer to a null terminated string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The library will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the library will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the library will return an error indicating that the certificate could not be found. If the SECURITY_PROTOCOL_SSH protocol has been specified, this member should be NULL.

lpszKeyFile

This member is not used and should always be NULL. The private key cannot be specified separately and must be associated with the certificate.

Remarks

An application only needs to create this structure if the server requires the client to provide a certificate as part of the process of negotiating the secure session. If a certificate is required, note that it must have a private key associated with it. Attempting to use a certificate that does not have a private key will result in an error during the connection process indicating that the client credentials could not be established.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user,

or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *dwOptions* member should be set to CREDENTIAL_STORE_FILENAME and the *lpCertStore* member should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. Note that if a password was specified when the certificate file was created, it must be provided in the *lpPassword* member or the library will be unable to access the certificate.

Note that the *lpUserName* and *lpPassword* members are values which are used to access the certificate store or private key file. They are not the credentials which are used when establishing the connection with the remote host or authenticating the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

The **SECURITYINFO** structure contains security related information about the connection, including the protocol, cipher suite and certificate.

```
typedef struct _SECURITYINFO
{
    DWORD        dwSize;
    DWORD        dwProtocol;
    DWORD        dwCipher;
    DWORD        dwCipherStrength;
    DWORD        dwHash;
    DWORD        dwHashStrength;
    DWORD        dwKeyExchange;
    DWORD        dwCertStatus;
    SYSTEMTIME    stCertIssued;
    SYSTEMTIME    stCertExpires;
    LPCTSTR       lpszCertIssuer;
    LPCTSTR       lpszCertSubject;
    LPCTSTR       lpszFingerprint;
} SECURITYINFO, *LPSECURITYINFO;
```

Members

dwSize

Specifies the size of the data structure. This member must always be initialized to the size of the structure in bytes prior to passing the address of this structure to the function. If this member is not initialized, an error will be returned indicating that an invalid parameter has been passed to the function.

dwProtocol

A numeric value which specifies the security protocol selected when establishing the connection.

Value	Description
SECURITY_PROTOCOL_NONE	The connection is not secure. This value indicates a standard connection was established and all other structure members will have a value of zero.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol was selected when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol was selected when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.

SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol was selected when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol was selected when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

dwCipher

A numeric value which specifies the cipher that was selected when establishing the secure connection.

Value	Description
SECURITY_CIPHER_AES	The Advanced Encryption Standard cipher is a fixed block size cipher which use a key size of 128, 192 or 256 bits.
SECURITY_CIPHER_DES	The Data Encryption Standard block cipher was selected. This is a fixed key length cipher, using 56-bit keys.
SECURITY_CIPHER_DES3	The Triple DES block cipher was selected. This cipher encrypts the data three times using different keys, effectively providing a 168-bit length key.
SECURITY_CIPHER_DESX	A variant of the DES block cipher which XORs an extra 64-bits of the key before and after the plaintext has been encrypted, increasing the key size to 184 bits.
SECURITY_CIPHER_RC4	The RC4 stream cipher was selected. This is a variable key length cipher which supports keys between 40 and 128 bits, in 8-bit increments.
SECURITY_CIPHER_RC5	The RC5 block cipher was selected. This is a variable key length cipher which supports keys up to 2040 bits, in 8-bit increments.

dwCipherStrength

A numeric value which specifies the strength (the length of the cipher key in bits) of the cipher that was selected. Typically this value will be 128 or 256. 40-bit and 56-bit key lengths are considered weak encryption, and subject to brute force attacks. 128-bit and 256-bit key lengths are considered to be secure, and are the recommended key length for secure communications.

dwHash

A numeric value which specifies the hash algorithm which was selected.

Value	Description
SECURITY_HASH_MD5	The MD5 algorithm was selected. Its use has been deprecated and is no longer considered to be cryptographically secure.
SECURITY_HASH_SHA1	The SHA-1 algorithm was selected. Its use has been deprecated and is no longer considered to be

	cryptographically secure.
SECURITY_HASH_SHA256	The SHA-256 algorithm was selected.
SECURITY_HASH_SHA384	The SHA-384 algorithm was selected.
SECURITY_HASH_SHA512	The SHA-512 algorithm was selected.

dwHashStrength

A numeric value which specifies the strength (the length in bits) of the message digest that was selected.

dwKeyExchange

A numeric value which specifies the key exchange algorithm which was selected.

Value	Description
SECURITY_KEYEX_RSA	The RSA public key algorithm was selected.
SECURITY_KEYEX_KEA	The Key Exchange Algorithm (KEA) was selected. This is an improved version of the Diffie-Hellman public key algorithm.
SECURITY_KEYEX_DH	The Diffie-Hellman key exchange algorithm was selected.
SECURITY_KEYEX_ECDH	The Elliptic Curve Diffie-Hellman key exchange algorithm was selected. This is a variant of the Diffie-Hellman algorithm which uses elliptic curve cryptography.

dwCertStatus

A numeric value which specifies the status of the certificate returned by the secure server.

Value	Description
SECURITY_CERTIFICATE_VALID	The certificate is valid.
SECURITY_CERTIFICATE_NOMATCH	The certificate is valid, but the domain name does not match the common name in the certificate.
SECURITY_CERTIFICATE_EXPIRED	The certificate is valid, but has expired.
SECURITY_CERTIFICATE_REVOKED	The certificate has been revoked and is no longer valid.
SECURITY_CERTIFICATE_UNTRUSTED	The certificate or certificate authority is not trusted on the local system.
SECURITY_CERTIFICATE_INVALID	The certificate is invalid. This typically indicates that the internal structure of the certificate has been damaged.

stCertIssued

A structure which contains the date and time that the certificate was issued by the certificate authority. If the issue date cannot be determined for the certificate, the SYSTEMTIME structure members will have zero values.

stCertExpires

A structure which contains the date and time that the certificate expires. If the expiration date cannot be determined for the certificate, the SYSTEMTIME structure members will have zero values.

lpszCertIssuer

A pointer to a string which contains information about the organization that issued the certificate. This string consists of one or more comma-separated tokens. Each token consists of an identifier, followed by an equal sign and a value. If the certificate issuer could not be determined, this member may be NULL.

lpzCertSubject

A pointer to a string which contains information about the organization that the certificate was issued to. This string consists of one or more comma-separated tokens. Each token consists of an identifier, followed by an equal sign and a value. If the certificate subject could not be determined, this member may be NULL.

lpzFingerprint

A pointer to a string which contains a sequence of hexadecimal values that uniquely identify the server. This member may be NULL.

Remarks

The size of this structure is typically determined using the **sizeof** operator in C/C++ and most other languages have a similar method for obtaining the size of a data structure or user-defined type. It is important to note the size of this structure will be different on 32-bit and 64-bit platforms due to the difference in the length of the structure members which are pointers.

When evaluating structure members which are string pointers, such as ***lpzCertIssuer*** and ***lpzCertSubject***, you should always check to ensure their values are not NULL (zero) before attempting to dereference them. If those values are undefined, it is not guaranteed they will point to zero-length strings.

There are additional protocols and ciphers defined which are not listed above because they are considered insecure and are no longer supported. It is important to note that most servers will reject attempts to use unsupported protocols such as SSL 3.0 and will either abort the connection or issue an error message and then immediately disconnect.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

SYSTEMTIME

The **SYSTEMTIME** structure represents a date and time using individual members for the month, day, year, weekday, hour, minute, second, and millisecond.

```
typedef struct _SYSTEMTIME
{
    WORD wYear;
    WORD wMonth;
    WORD wDayOfWeek;
    WORD wDay;
    WORD wHour;
    WORD wMinute;
    WORD wSecond;
    WORD wMilliseconds;
} SYSTEMTIME, *LPSYSTEMTIME;
```

Members

wYear

Specifies the current year. The year value must be greater than 1601.

wMonth

Specifies the current month. January is 1, February is 2 and so on.

wDayOfWeek

Specifies the current day of the week. Sunday is 0, Monday is 1 and so on.

wDay

Specifies the current day of the month

wHour

Specifies the current hour.

wMinute

Specifies the current minute

wSecond

Specifies the current second.

wMilliseconds

Specifies the current millisecond.

Hypertext Transfer Queue Class Library

Manage a queue which will perform HTTP file transfers in the background.

Reference

- [Class Methods](#)
- [Data Structures](#)
- [Error Codes](#)

Library Information

File Name	CSHTPV11.DLL
Version	11.0.2218.1855
LibID	1EE620E7-5A9E-4DC3-8403-9153F19C51D9
Import Library	CSHTPV11.LIB
Dependencies	None
Standards	RFC 1945, RFC 2616, RFC 7230, RFC 7540

Overview

The Hypertext Transfer Queue class library provides a high-level interface to uploading and downloading a collection of files using the Hypertext Transfer Protocol. Queued file transfers are performed in a background worker thread, with optional event notifications to inform the application about the current state of the queue and the files being processed.

A file may be queued for upload or download, and both uploads and downloads may be included in the same queue. Multiple instances of this class may be created to transfer multiple files at the same time. This class supports the same options available to individual file transfers using the [CHttpClient](#) class.

This class supports secure, encrypted file transfers using TLS 1.2 and later versions of the protocol.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This class is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the

system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

Hypertext Transfer Queue Class Methods

Class	Description
CHttpQueue	Constructor which initializes the current instance of the class
~CHttpQueue	Destructor which releases resources allocated by the class
Method	Description
AddFile	Add a file to the transfer queue
AttachHandle	Attach the specified client handle to this instance of the class
Cancel	Cancel the specified queued file transfer
Clear	Remove all files from the transfer queue
DetachHandle	Detach the handle for the current instance of this class
DisableTrace	Disable logging of socket function calls to the trace log
EnableTrace	Enable logging of socket function calls to a file
EnumFiles	Enumerate queued files based on the specified criteria
FindFile	Find a specific file in the queue
HttpEventProc	Callback function that processes events generated during queued transfers
GetClient	Return a handle to the active client session during a queued file transfer
GetCount	Return the number of files queued for transfer
GetErrorString	Return a description for the specified error code
GetFile	Return information about the specified file
GetFirstFile	Return information about the first file in the transfer queue
GetHandle	Return a handle for the queue
GetLastError	Return the last error code
GetNextFile	Return information about the next file in the transfer queue
GetStatus	Return the current status of the file transfer queue
GetTransferStatus	Return information about the file being currently transferred
IsEmpty	Determine if the current file transfer queue is empty
IsIdle	Determine if the queue manager is currently idle
IsInitialized	Determine if the class has been successfully initialized
RemoveFile	Remove a file from the transfer queue
Reset	Reset the internal state of file transfers in the queue
Resume	Resume the transfer of files after queue processing has been paused
SetLastError	Set the last error code
ShowError	Display a message box with a description of the specified error
Start	Begin transferring files in the queue

Stop	Stop transferring files in the queue
Suspend	Pause the transfer of files in the queue
Wait	Wait for the transfer of all queued files to complete

CHttpQueue::CHttpQueue Method

```
CHttpQueue();  
  
CHttpQueue(  
    UINT nMaxFiles,  
    UINT nTimeout,  
    DWORD dwOptions  
);
```

The **CHttpQueue** constructor initializes the class library and validates the license key at runtime.

Parameters

nMaxFiles

An unsigned integer which specifies the maximum number of files which can be added to the queue. The constant INFINITE can be used to specify that there is no fixed limit to the number of files in the queue.

nTimeout

An unsigned integer which specifies the default timeout for all queued file transfers. If this value is zero, a reasonable default timeout period will be used. This timeout period is used when a file is added to the queue without providing a timeout period for that specific file transfer. If a timeout period is specified for a particular file, it will override this value.

dwOptions

An unsigned integer value which specifies one or more default options for all queued files. This parameter is constructed by using a bitwise operator and can be any of the options used with the **CHttpClient::Connect** method. If transfer options are specified for a particular file, it will override this value. The most common options are:

Value	Description
HTTP_OPTION_DEFAULT	Default options should be used for queued file transfers. This is the same as specifying that all file transfers should use passive mode when establishing a data connection with the server. It is recommended most applications use passive mode to prevent potential compatibility issues with certain types of firewalls and routers which use Network Address Translation (NAT).
HTTP_OPTION_FIREWALL	This option specifies queued transfers should always use the host IP address to establish the data connection with the server, not the address returned by the server in response to the PASV command. This option may be necessary if the server is behind a router that performs Network Address Translation (NAT) and it returns an unreachable IP address for the data connection. If this option is specified, it will also enable passive mode data transfers.
HTTP_OPTION_SECURE	This option specifies queued file transfers should attempt to establish a secure connection with the server by default. This option is the same as specifying

	HTTP_OPTION_SECURE_IMPLICIT which immediately performs the TLS protocol negotiation when the connection is established.
HTTP_OPTION_SECURE_IMPLICIT	This option specifies queued file transfers should attempt to immediately establish secure TLS connection with the server by default. This option is typically used when connecting to a server on port 990, which is the default port number used for HTTPS.
HTTP_OPTION_SECURE_EXPLICIT	This option specifies queued file transfers should establish a standard connection to the server and then use the AUTH command to negotiate an explicit secure connection. This option is typically used when connecting to the server on ports other than 990.
HTTP_OPTION_SECURE_SHELL	This option specifies queued file transfers should use the Secure Shell (SSH) protocol to establish the connection by default. This option will automatically be selected if the connection is established using port 22, the default port for SSH.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

If the *nMaxFiles* parameter is INFINITE, memory will be dynamically allocated on the process heap with no limit to the number of files which can be queued. If there is a logic error which causes the application to recursively add files to the queue, or repeatedly queue the same file, this can result in virtual memory being exhausted for the process. You can avoid this by specifying a reasonable maximum queue size, which will cause the **AddFile** method to fail if that limit is exceeded.

When called without any parameters, the constructor will create a queue with no file limit, default options and a default timeout period. The memory allocated for the queue will be released when the class destructor is invoked.

The constructor calls the **HttpInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[~CHttpRequest](#), [IsInitialized](#), [CHttpClient::Connect](#)

CHttpRequest::~CHttpRequest

`~CHttpRequest();`

The **CHttpRequest** destructor releases resources allocated by the current instance of the **CHttpRequest** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CHttpRequest** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

[CHttpRequest](#)

CHttpQueue::AddFile Method

```
DWORD AddFile(  
    DWORD dwQueueMode,  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions,  
    UINT nTimeout  
);  
  
DWORD AddFile(  
    DWORD dwQueueMode,  
    LPCTSTR lpszHostName,  
    UINT nHostPort,  
    UINT nAuthType,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    LPCTSTR lpszLocalFile,  
    LPCTSTR lpszRemoteFile,  
    DWORD dwOptions,  
    UINT nTimeout  
);
```

The **AddFile** method adds a new file to the queue with additional transfer options.

Parameters

dwQueueMode

An integer value which specifies if the file should be downloaded from the server or uploaded to the server. This parameter must be one of the following options and cannot have a value of zero.

Constant	Description
HTTP_QUEUE_DOWNLOAD	The file should be queued for downloading from the server to the local system.
HTTP_QUEUE_UPLOAD	The file should be queued for uploading from the local system to the server.

lpszHostName

A pointer to the name of the server to establish a connection with. This may be a fully-qualified domain name or an IP address. If this parameter is NULL or points to an empty string, the *lpszRemoteFile* parameter must specify a complete URL which identifies the server as well as the path to the remote file.

nHostPort

The port number which should be used when establishing the connection. A value of zero specifies that the default port number should be used. For standard connections, the default port number is 21. For secure connections, the default port number is 990. If this parameter is zero and a URL is specified with the *lpszRemoteFile* parameter, the port number included in the URL will be used as the default value.

nAuthType

An unsigned integer value which specifies the method to be used when authenticating the client. The following values are supported:

--	--

Value	Description
HTTP_AUTH_NONE	No client authentication should be performed. The <i>lpszUserName</i> and <i>lpszPassword</i> parameters are ignored and current authentication settings are cleared.
HTTP_AUTH_BASIC	The Basic authentication scheme should be used. This option is supported by all servers that support at least version 1.0 of the protocol. The user credentials are not encrypted and Basic authentication should not be used over standard (non-secure) connections. Most web services which use Basic authentication require the connection to be secure.
HTTP_AUTH_BEARER	The Bearer authentication scheme should be used. This authentication method does not require a user name and the <i>lpszPassword</i> parameter must specify the OAuth 2.0 bearer token issued by the service provider. If the access token has expired, the request will fail with an authorization error.

lpszUserName

Points to a null terminated string which specifies the user name to be used to authenticate the connection. If this parameter is NULL or an empty string, no client credentials are provided. If the authentication type is HTTP_AUTH_BEARER, this parameter is ignored.

lpszPassword

Points to a null terminated string which specifies the password to be used to authenticate the current client session. This parameter may be NULL or an empty string if no password is required for the specified user, or if no username has been specified. If the authentication type is HTTP_AUTH_BEARER, this value must be the bearer token issued by the service provider.

lpszLocalFile

A pointer to a null terminated string which specifies the name of the local file to be queued for transfer. This parameter cannot be NULL or point to an empty string. If the file is being queued for an upload, the file must exist on the local system or the method will fail. If the file is being downloaded, it will be created or replaced on the local system.

lpszRemoteFile

A pointer to a null terminated string which specifies the name of the file on the server. If the file is being downloaded, the file must exist on the server or the transfer will fail. If the file is being uploaded, the file will be created or replaced on the server. This parameter may specify a complete URL. Note that any values you specify as arguments to this method will override the values specified in the URL. If you want to use a URL as the remote file name, the *lpszHostName* parameter should be NULL and the *nHostPort* parameter should be zero.

dwOptions

An unsigned integer value which specifies one or more options. This parameter is constructed by using a bitwise operator and can be any of the options used with the **HttpClient::Connect** method. If this value is zero, the default options for the queue will be used. The most common options are:

Value	Description
HTTP_OPTION_DEFAULT	Default options should be used for the queued transfer. All standard headers will be included with the request and redirected resources will return an error, allowing the application to determine if it should request the resource from

	the new location or inform the user the resource location has changed.
HTTP_OPTION_REDIRECT	This option specifies the client should automatically handle resource redirection. If the server indicates that the requested resource has moved to a new location, the client will close the current connection and request the resource from the new location. Note that it is possible that the redirected resource will be located on a different server.
HTTP_OPTION_PROXY	This option specifies the client should use the default proxy configuration for the local system. If the system is configured to use a proxy server, then the connection will be automatically established through that proxy; otherwise, a direct connection to the server is established. The local proxy configuration can be changed in the system settings or control panel.
HTTP_OPTION_HTTP2	This option specifies the client should attempt a HTTP/2 connection with the server. If a connection cannot be established using HTTP/2 the client will attempt to connect using an earlier version of the protocol.
HTTP_OPTION_SECURE	This option specifies the client should attempt to establish a secure connection with the server. Note that the server must support secure connections using the TLS protocol. The client will default to using TLS 1.2 or later for secure connections.

nTimeout

The number of seconds to wait for a response from the server before failing the file transfer. If this value is zero, the default timeout period for the queue will be used.

lpvReserved

A reserved parameter which should always be NULL.

Return Value

If the method succeeds, the return value is a unique identifier which corresponds to the queued file. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will add a file to the current transfer queue. If successful, the value returned is a unique integer which identifies that file in the queue. To obtain information about the queued file, you can call the **GetFile** method and provide this return value as the *dwFileId* parameter. To remove a file from the queue, use the **RemoveFile** method.

Files can only be added to the queue when in an idle or paused state. If you attempt to add a file to the queue while the queue manager is transferring files, the method will fail. To determine the current state of the queue, call the **GetStatus** method

There are no fixed limits to the number of files which can be queued for transfer. To release the memory allocated for the queue, call the **Clear** method. To determine the current status of the queue, including how many file transfers have been queued and how many are pending completion, call the **GetStatus** method.

If the local file name includes environment variables enclosed in percentage (%) symbols, those values will automatically be expanded based on the environment variables defined for the current user using

the **ExpandEnvironmentStrings** function in the Windows API. Note that environment variable names are not case-sensitive.

This method will not immediately begin the process of uploading or downloading the file. It will only add the transfer request to the current queue. The file transfers are managed by a background worker thread which is created when the **Start** method is called.

Example

```
// Create a new queue
CHttpQueue pQueue = new CHttpQueue();

if (!pQueue->IsInitialized())
    return;

// Add a file to the queue
DWORD dwFileId = pQueue->AddFile(
    HTTP_QUEUE_DOWNLOAD,
    lpszHostName,
    HTTP_PORT_DEFAULT,
    lpszUserName,
    lpszPassword,
    lpszLocalFile,
    lpszRemoteFile);

// Display information about the queued file
if (dwFileId != 0)
{
    HTTPQUEUEDFILE queuedFile;

    if (pQueue->GetFile(dwFileId, &queuedFile))
    {
        switch (queuedFile.dwMode)
        {
            case HTTP_QUEUE_DOWNLOAD:
                _tprintf(_T("%u: Download \"%s\" to \"%s\"\n"),
                    dwFileId,
                    queuedFile.szRemoteFile,
                    queuedFile.szLocalFile);
                break;

            case HTTP_QUEUE_UPLOAD:
                _tprintf(_T("%u: Upload \"%s\" to \"%s\"\n"),
                    dwFileId,
                    queuedFile.szLocalFile,
                    queuedFile.szRemoteFile);
                break;
        }
    }
}

// Start the queued file transfers and wait for it to complete
if (pQueue->Start())
{
    pQueue->Wait(INFINITE);
    pQueue->Stop();
}

// Remove all files from the queue
```

```
delete pQueue;
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CHttpQueue](#), [~CHttpQueue](#), [FindFile](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#), [RemoveFile](#)

CHttpRequest::AttachHandle Method

```
VOID AttachHandle(  
    HQUEUE hQueue  
);
```

The **AttachHandle** method attaches the specified queue handle to the current instance of the class.

Parameters

hQueue

A handle to the queue.

Return Value

None.

Remarks

This method is used to attach a queue handle created outside of the class using the SocketTools API. Once the handle is attached to the class, the other class member functions may be used with that queue.

If a handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous queue from being destroyed, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hQueue* parameter is presumed to be a valid queue handle and no checks are performed to ensure that the handle is valid. Specifying an invalid queue handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[DetachHandle](#), [GetHandle](#)

CHttpQueue::Cancel Method

```
BOOL Cancel(  
    DWORD dwFileId  
);
```

The **Cancel** method cancels the specified file transfer.

Parameters

dwFileId

An optional unsigned integer value which uniquely identifies the file in the queue. If this parameter is omitted or the value is zero, the method will cancel the current file transfer in progress. If queue transfers have been suspended, this parameter cannot be zero.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

When this method is called, the queued file transfer may not immediately stop. An internal flag is set which causes the file transfer to exit with an error and the queue manager will begin processing the next file in the queue. If the queue is in an idle state, this method will fail.

It is permitted to call the **Cancel** method from within a queue event handler to cancel the current file transfer. In this case, the *dwFileId* parameter should be zero. If you specify a file which has not been transferred, it will be flagged as canceled and skipped by the queue manager when processing the queue. If you specify a file which has already been processed, this method will fail.

A canceled file transfer is also considered a failed transfer. When you call **GetStatus** after a queued file transfer is canceled, the *dwFailedFiles* member of the [HTTPQUEUESTATUS](#) structure will be incremented to reflect this change. You can determine the status of an individual file transfer by calling the **GetFile** method and checking the value of the *dwQueueFlags* member of the [HTTPQUEUEDFILE](#) structure.

The **Reset** method can be used to reset the state of previously canceled transfers.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[Cancel](#), [GetFile](#), [GetStatus](#), [Reset](#), [Resume](#), [Start](#), [Suspend](#), [Stop](#)

CHttpQueue::Clear Method

BOOL Clear();

The **Clear** method removes all files from the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method can only be called when the queue is in an idle state. An error will be returned if the method is called while the queue manager is paused or actively transferring files in the queue. To determine the current state of the queue, call the **GetStatus** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[Cancel](#), [GetStatus](#), [Reset](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#)

CHttpQueue::DetachHandle Method

```
HQUEUE DetachHandle();
```

The **DetachHandle** method detaches the queue handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the queue handle associated with the current instance of the class object. If an error occurs, the value `INVALID_QUEUE` will be returned.

Remarks

This method is used to detach a queue handle created by the class for use with the SocketTools API. Once the handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `cshttpv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CHttpRequest::DisableTrace Method

```
BOOL DisableTrace();
```

The **DisableTrace** method disables the logging of socket function calls to the trace log.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, a value of zero is returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[EnableTrace](#)

CHttpQueue::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of network function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads. This option is always selected for the CHttpQueue class.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the server.

Trace method logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisableTrace](#)

CHttpRequest::EnumFiles Method

```
LONG EnumFiles(  
    LPCTSTR lpszFileMask,  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles,  
    LPDWORD lpFileList,  
    LONG nMaxFiles  
);
```

The **EnumFiles** method returns a list of files in the current transfer queue.

Parameters

lpszFileMask

A pointer to a null terminated string which specifies a file name which can include wildcards. Only those files which match this value will be enumerated. The character '?' will match against any single character, and '*' will match any number of characters. If this parameter is NULL or points to an empty string, all eligible files in the queue will be matched.

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. Only those files which match the queue mode will be enumerated. This is a bitmask which may be one or more of the following values:

Constant	Description
HTTP_QUEUE_ALL	Match the file name to all files in the queue.
HTTP_QUEUE_DOWNLOAD	Match file names which are queued for download.
HTTP_QUEUE_UPLOAD	Match file names which are queued for upload.
HTTP_QUEUE_LOCAL	Match against the local file name instead of the remote file name.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the enumeration. If this value is zero, no files will be excluded; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_QUEUE_FLAG_NONE	No files should be excluded.
HTTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
HTTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
HTTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of

lpFileList

A pointer to an array of unsigned integer values which will contain the unique file identifiers for each matching file in the queue. This parameter must specify an array large enough to store all of the file identifiers, otherwise the method will fail with a **ST_ERROR_BUFFER_TOO_SMALL** error. If this parameter is NULL, the method will return the number of matching files.

nMaxFiles

An integer value which specifies the maximum number of file identifiers which can be copied into the *lpFileList* array. If the *lpFileList* parameter is not NULL, this value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of matching files. If the queue is empty or there are no matching files, this method will return zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method populates an array of unique file identifiers which can be used to obtain information about the files in the current queue. The values returned in the *lpFileList* array can be used in conjunction with the **GetFile** method. This provides an alternative to using the **GetFirstFile** and **GetNextFile** methods.

The application should not make any assumptions about the value of the file identifiers returned by this method. They should be considered opaque values which are only guaranteed to uniquely identify a file in the transfer queue. In particular, there is no guarantee that the file identifiers will be sequential and they should not be used as index values into an array.

Example

```
// Get the total number of files in the queue
LONG nFiles = pQueue->GetCount();

// Display information about the queued files
if (nFiles > 0)
{
    DWORD *pdwFileList = new DWORD[nFiles];
    nFiles = pQueue->EnumFiles(NULL, HTTP_QUEUE_ALL, HTTP_QUEUE_FLAG_NONE,
pdwFileList, nFiles);

    for (LONG nIndex = 0; nIndex < nFiles; nIndex++)
    {
        HTTPQUEUEDFILE queuedFile;

        if (pQueue->GetFile(pdwFileList[nIndex], &queuedFile) == FALSE)
            break;

        switch (queuedFile.dwMode)
        {
        case HTTP_QUEUE_DOWNLOAD:
            _tprintf(_T("%u: Download \"%s\" to \"%s\"\\n"),
                queuedFile.dwFileId,
                queuedFile.szRemoteFile,
                queuedFile.szLocalFile);
            break;

        case HTTP_QUEUE_UPLOAD:
```

```
        _tprintf(_T("%u: Upload \"%s\" to \"%s\"\\n"),
                queuedFile.dwFileId,
                queuedFile.szLocalFile,
                queuedFile.szRemoteFile);
        break;
    }
}

delete pdwFileList;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpQueue::FindFile Method

```
DWORD FindFile(  
    LPCTSTR lpszFileName,  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles  
);
```

The **FindFile** method finds a file in the transfer queue which matches the search criteria.

Parameters

lpszFileName

A pointer to a null terminated string which specifies the name of the file to search for. The string may contain the wildcard character '?' to match against any single character, and '*' will match any number of characters. This parameter cannot be NULL or point to an empty string.

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. This is a bitmask which may be one or more of the following values:

Constant	Description
HTTP_QUEUE_ALL	Match the file name to all files in the queue.
HTTP_QUEUE_DOWNLOAD	Match file names which are queued for download.
HTTP_QUEUE_UPLOAD	Match file names which are queued for upload.
HTTP_QUEUE_LOCAL	Match against the local file name instead of the remote file name.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the search. If this value is zero, no files will be excluded from the search; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_QUEUE_FLAG_NONE	No files should be excluded from the search.
HTTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
HTTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
HTTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

Return Value

If the method succeeds, the return value is a unique identifier for the file. To obtain information about the file, call the **GetFile** method. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns a unique file identifier for the first file which matches the specified file name in the queue. If the *lpzFileName* parameter includes wildcard characters, this method will return the first file in the queue which matches the name. File name matches are not case-sensitive, even when matching against remote file names on servers which use case-sensitive naming, such as UNIX based servers.

To perform more complex searches based on the file name, or to find multiple files, you can use the **GetFirstFile** and **GetNextFile** methods to iterate through all queued files.

Example

```
// Find a local file in the download queue
DWORD dwFileId = pQueue->FindFile(lpzFileName,
                                   HTTP_QUEUE_DOWNLOAD | HTTP_QUEUE_LOCAL,
                                   HTTP_QUEUE_FLAG_NONE);

// Display information about the queued file
if (dwFileId != 0)
{
    HTTPQUEUEDFILE queuedFile;

    if (pQueue->GetFile(dwFileId, &queuedFile))
    {
        switch (queuedFile.dwMode)
        {
            case HTTP_QUEUE_DOWNLOAD:
                _tprintf(_T("%u: Download \"%s\" to \"%s\"\n"),
                        dwFileId,
                        queuedFile.szRemoteFile,
                        queuedFile.szLocalFile);
                break;

            case HTTP_QUEUE_UPLOAD:
                _tprintf(_T("%u: Upload \"%s\" to \"%s\"\n"),
                        dwFileId,
                        queuedFile.szLocalFile,
                        queuedFile.szRemoteFile);
                break;
        }
    }
}
```

Requirements

CHttpQueue::GetClient Method

HCLIENT GetClient();

The **GetClient** method returns a handle to the current client session.

Parameters

None.

Return Value

If the method succeeds, the return value is a handle to a client session. If the method fails, it will return **INVALID_CLIENT**. To get extended error information, call **GetLastError**.

Remarks

The **GetClient** method returns the handle to a client session which may be used with other methods. A valid handle will only be returned if the queue manager is currently uploading or downloading a file. If the queue is active but there are no file transfers in progress at the time this method is called, it will fail and set the last error code to **ST_ERROR_NO_QUEUED_TRANSFER**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[CHttpQueue](#), [~CHttpQueue](#), [GetTransferStatus](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#)

CHttpQueue::GetCount Method

```
LONG GetCount();
```

The **GetCount** method returns the total number of files which have been queued for transfer.

Parameters

None.

Return Value

If the method succeeds, the return value is the number of files in the queue. If the method fails, it will return HTTP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

See Also

[CHttpQueue](#), [~CHttpQueue](#), [EnumFiles](#), [GetStatus](#), [GetFile](#), [GetFirstFile](#), [GetNextFile](#)

CHttpRequest::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT cbDescription  
);  
  
INT GetErrorString(  
    DWORD dwErrorCode,  
    CString& strDescription  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length. An alternate form of the method accepts a **CString** variable which will contain the error description.

cbDescription

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is zero, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLastError](#), [SetLastError](#), [ShowError](#)

CHttpRequest::GetFile Method

```
BOOL GetFile(
    LPCTSTR lpszFileName,
    LPHTTPQUEUEDFILE lpFileInfo
);

BOOL GetFile(
    DWORD dwFileId,
    LPHTTPQUEUEDFILE lpFileInfo
);
```

The **GetFile** method returns information about the specified file in the transfer queue.

Parameters

lpszFileName

A pointer to a null terminated string which specifies the name of the file in the queue. The name should always be the name of the remote file to search for.

dwFileId

An unsigned integer value which uniquely identifies the file in the queue. This value cannot be zero.

lpFileInfo

A pointer to a [HTTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the file identifier is not valid or the file has been removed from the queue, the return value is zero. To get extended error information, call **HttpGetLastError**.

Remarks

The file identifier can be obtained by several different methods, including **EnumFiles** and **GetStatus**, which provides information about the current file being processed in the queue. Do not make any assumptions about the value of the identifier. Although the value is guaranteed to be unique for the specified queue, it is not guaranteed that file identifiers will be assigned in sequential order.

If you call the version of this method which accepts a file name, it will use the **FindFile** method to obtain the file ID for the first file name which matches a remote file in the queue. This approach is only recommended if you know that the queued file names will be unique.

Example

```
// Get the number of files in the queue
LONG nFiles = pQueue->GetCount();

// Display information about the queued files
if (nFiles > 0)
{
    DWORD *pdwFileList = new DWORD[nFiles];

    nFiles = pQueue->EnumFiles(pdwFileList, nFiles);

    for (LONG nIndex = 0; nIndex < nFiles; nIndex++)
    {
        HTTPQUEUEDFILE queuedFile;
```

```

        if (pQueue->GetFile(pdwFileList[nIndex], &queuedFile) == FALSE)
            break;

        switch (queuedFile.dwMode)
        {
        case HTTP_QUEUE_DOWNLOAD:
            _tprintf(_T("%u: Download \"%s\" to \"%s\"\\n"),
                    queuedFile.dwFileId,
                    queuedFile.szRemoteFile,
                    queuedFile.szLocalFile);
            break;

        case HTTP_QUEUE_UPLOAD:
            _tprintf(_T("%u: Upload \"%s\" to \"%s\"\\n"),
                    queuedFile.dwFileId,
                    queuedFile.szLocalFile,
                    queuedFile.szRemoteFile);
            break;
        }
    }

    delete pdwFileList;
}

```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpQueue::GetFirstFile Method

```
DWORD GetFirstFile(  
    DWORD dwQueueMode,  
    DWORD dwExcludeFiles,  
    LPHTTPQUEUEDFILE lpFileInfo  
);
```

The **HttpGetFirstFile** method returns information about the first file in the transfer queue.

Parameters

dwQueueMode

An unsigned integer value which specifies if the file name should be matched against downloaded files, uploaded files or all files in the queue. It may be one of the following values:

Constant	Description
HTTP_QUEUE_ALL	Return information about all files in the queue.
HTTP_QUEUE_DOWNLOAD	Return information for files which are queued for download.
HTTP_QUEUE_UPLOAD	Return information for files which are queued for upload.

dwExcludeFiles

An unsigned integer value which specifies which files to exclude from the search. If this value is zero, no files will be excluded from the search; otherwise, this value is constructed by using a bitwise operator with any of the following values:

Value	Description
HTTP_QUEUE_FLAG_NONE	No files should be excluded.
HTTP_QUEUE_FLAG_COMPLETED	Exclude files which have been transferred. This flag is set after a queued file has been uploaded or downloaded successfully.
HTTP_QUEUE_FLAG_FAILED	Exclude files which were not successfully uploaded or downloaded. This flag is set when an error occurs, either when establishing a connection with the server or during the file transfer.
HTTP_QUEUE_FLAG_CANCELED	Exclude files which were canceled during the file transfer. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

lpFileInfo

A pointer to a [HTTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is an unsigned integer with a non-zero value which uniquely identifies the file in the queue. If there are no queued files which match the specified parameters, or

the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns information about the first file in the current transfer queue. It is used in conjunction with the **GetNextFile** method to obtain information about all queued files.

Example

```
// List all files in a file transfer queue
HTTPQUEUEDFILE queuedFile;
DWORD dwFileId;

dwFileId = pQueue->GetFirstFile(HTTP_QUEUE_ALL, HTTP_QUEUE_FLAG_NONE, &queuedFile);

while (dwFileId != 0)
{
    switch (queuedFile.dwQueueMode)
    {
    case HTTP_QUEUE_DOWNLOAD:
        _tprintf(_T("%u: download \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szRemoteFile,
            queuedFile.szLocalFile);
        break;

    case HTTP_QUEUE_UPLOAD:
        _tprintf(_T("%u: upload \"%s\" to \"%s\"\\n"),
            queuedFile.dwFileId,
            queuedFile.szRemoteFile,
            queuedFile.szLocalFile);
        break;
    }

    dwFileId = pQueue->GetNextFile(&queuedFile);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpQueue::GetHandle Method

```
HQUEUE GetHandle();
```

The **GetHandle** method returns the queue handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the queue handle associated with the current instance of the class object. If an error occurs, the value `INVALID_QUEUE` will be returned.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `cshttpv11.lib`

See Also

CHttpRequest::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or HTTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[GetErrorString](#), [SetLastError](#), [ShowError](#)

CHttpRequest::GetNextFile Method

```
DWORD GetNextFile(  
    LPHTTPQUEUEDFILE lpFileInfo  
);
```

The **GetNextFile** method returns information about the next file in the transfer queue.

Parameters

lpFileInfo

A pointer to a [HTTPQUEUEDFILE](#) structure which will contain information about the file. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is an unsigned integer with a non-zero value which uniquely identifies the file in the queue. If there are no additional queued files which match the exclusion criteria specified with the call to **GetFirstFile**, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method returns information about the next file in the current transfer queue after an initial call to **GetFirstFile**. To obtain a list of all matching files in the queue, call this method repeatedly until it returns a value of zero. When information about the last file in the queue has been returned, the last error code will be set to **ST_ERROR_END_OF_QUEUE**.

Example

```
// List all files in a file transfer queue  
HTTPQUEUEDFILE queuedFile;  
DWORD dwFileId;  
  
dwFileId = pQueue->GetFirstFile(HTTP_QUEUE_ALL, HTTP_QUEUE_FLAG_NONE, &queuedFile);  
  
while (dwFileId != 0)  
{  
    switch (queuedFile.dwQueueMode)  
    {  
        case HTTP_QUEUE_DOWNLOAD:  
            _tprintf(_T("%u: download \"%s\" to \"%s\"\\n"),  
                    queuedFile.dwFileId,  
                    queuedFile.szRemoteFile,  
                    queuedFile.szLocalFile);  
            break;  
  
        case HTTP_QUEUE_UPLOAD:  
            _tprintf(_T("%u: upload \"%s\" to \"%s\"\\n"),  
                    queuedFile.dwFileId,  
                    queuedFile.szRemoteFile,  
                    queuedFile.szLocalFile);  
            break;  
    }  
  
    dwFileId = pQueue->GetNextFile(&queuedFile);  
}
```

Requirements

CHttpQueue::GetStatus Method

```
INT GetStatus(  
    LPHTTPQUEUESTATUS LpQueueStatus  
);
```

The **GetStatus** method returns information about the specified file in the transfer queue.

Parameters

LpQueueStatus
A pointer to a [HTTPQUEUESTATUS](#) structure which will contain information about the current state of the file transfer queue. If this parameter is NULL, the method will ignore the parameter and only return the current status of the queue.

Return Value

If the method succeeds, the return value is the current queue status. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **HttpGetLastError**. The following status values may be returned:

Value	Description
HTTP_QUEUE_STATUS_IDLE	The file transfer queue is idle and no files are being uploaded or downloaded. This state is returned before HttpStartQueue has been called or after HttpStopQueue has been called. The queue will also automatically enter an idle state after the last file transfer has completed and the queue manager thread exits.
HTTP_QUEUE_STATUS_ACTIVE	The queue manager is active and files are currently being uploaded or downloaded.
HTTP_QUEUE_STATUS_PAUSED	The queue manager is active although file transfers are currently paused. The queue enters this state after the HttpSuspendQueue method is called and resumes file transfers after the HttpResumeQueue method is called.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** cshttpv11.lib

CHttpRequest::GetTransferStatus Method

```
INT GetTransferStatus(  
    LPHTTPTRANSFERSTATUS LpStatus  
);  
  
INT GetTransferStatus(  
    LPHTTPTRANSFERSTATUSEX LpStatus  
);
```

The **GetTransferStatus** method returns information about the current file transfer in progress.

Parameters

LpStatus

A pointer to an [HTTPTRANSFERSTATUS](#) or [HTTPTRANSFERSTATUSEX](#) structure which contains information about the status of the current file transfer.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **GetTransferStatus** method returns information about the current file transfer, including the average number of bytes transferred per second and the estimated amount of time until the transfer completes. This method would typically be called from within a callback function in response to an HTTP_EVENT_PROGRESS event notification.

The *dwBytesTotal* and *dwBytesCopied* members of the **HTTPTRANSFERSTATUSEX** structure are declared as unsigned 64-bit integers rather than 32-bit integers. To obtain accurate file transfer information, this extended version of the structure should be used with files that are larger than 4GiB.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpQueue::IsEmpty Method

BOOL IsEmpty();

The **IsEmpty** method determines if the current queue is empty.

Parameters

None.

Return Value

If no files have been added to the queue, the return value is non-zero. If one or more files have been added to the queue, the method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtpv11.lib

See Also

[AddFile](#) [Clear](#) [GetFile](#), [IsIdle](#), [RemoveFile](#)

CHttpQueue::IsIdle Method

BOOL IsIdle();

The **IsIdle** method determines if the queue is idle.

Parameters

None.

Return Value

If the queue is idle and no files are being transferred, this method returns a non-zero value. If the queue manager is currently transferring files, the return value is zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AddFile](#), [Cancel](#), [Clear IsEmpty](#), [Reset](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#), [Wait](#)

CHttpQueue::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshttpv11.lib

CHttpRequest::RemoveFile Method

```
BOOL RemoveFile(  
    DWORD dwFileId  
);  
  
BOOL RemoveFile(  
    LPCTSTR lpszFileName  
);
```

The **RemoveFile** method removes the specified file from the queue.

Parameters

dwFileId

An unsigned integer value which uniquely identifies the file in the queue. This value cannot be zero.

lpszFileName

A pointer to a null terminated string which specifies the name of the file to remove. If this version of the method is called, this parameter cannot be NULL or point to an empty string. The file name may include wildcard characters if you wish to remove multiple files. The character '?' will match against any single character, and '*' will match any number of characters.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **HttpGetLastError**.

Remarks

Files can only be removed from the queue when in an idle or paused state. If you attempt to remove a file while the queue manager is in the process of uploading or download files, the method will fail.

The file identifier can be obtained by several different methods, including **EnumFiles** and **GetStatus**, which provides information about the current file being processed in the queue. Do not make any assumptions about the value of the identifier. Although the value is guaranteed to be unique for the specified queue, it is not guaranteed that file identifiers will be assigned in sequential order.

If you call this method using a file name, the **EnumFiles** method will be used to enumerate all remote file names which match and remove them from the queue. File name matches are not case-sensitive, even when matching against file names on servers which use case-sensitive naming, such as UNIX based servers.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AddFile](#) [Clear](#) [IsEmpty](#), [Reset](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#)

CHttpRequest::Reset Method

```
BOOL Reset(  
    DWORD dwOptions  
);
```

The **Reset** method resets the state of all file transfers in the current queue.

Parameters

dwOptions

An integer value which specifies which files should be reset in the queue. It may be one of the following values:

Value	Description
HTTP_QUEUE_RESET_ALL	All files in the queue should be reset to their initial state.
HTTP_QUEUE_RESET_COMPLETED	All files in the queue which have been successfully transferred will be reset to their initial state.
HTTP_QUEUE_RESET_FAILED	All files in the queue which were not transferred will be reset to their initial state.
HTTP_QUEUE_RESET_CANCELED	All files in the queue which were canceled will be reset to their initial state.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

When the **Start** method is called multiple times, it will not attempt to transfer files which have already been successfully copied, and it will not attempt to re-transfer files if the previous transfer failed. This method resets queued files back to their initial state, prior to when the queue manager attempted to perform the transfer. The most common use would be to call the method with the HTTP_QUEUE_RESET_FAILED mode and then call **Start** to retry failed or canceled file transfers.

Because canceled file transfers are also considered failed transfers, specifying HTTP_QUEUE_RESET_FAILED will reset queued files which either encountered an error during the transfer or were explicitly canceled by calling the **Cancel** method. The HTTP_QUEUE_RESET_CANCELED option will only reset the state of queued file transfers which were canceled.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[AddFile](#), [Cancel](#), [Clear](#), [IsEmpty](#), [Resume](#), [Start](#), [Stop](#), [Suspend](#), [Wait](#)

CHttpQueue::Resume Method

```
BOOL Resume();
```

The **Resume** method resumes transfers in the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method signals the queue manager to resume processing files in the transfer queue after the **Suspend** method has been called. This method will fail if the queue is in an idle (stopped) state, and will be ignored if the queue manager is already transferring files. The **GetStatus** method can be called to obtain the current status of the queue.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

CHttpRequest::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the last error code for the current thread. This method is typically used to clear the last error by specifying a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the last error code for the current thread.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Failure is typically indicated by a return value such as FALSE, NULL, INVALID_QUEUE or HTTP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by calling the **GetLastError** method. The use of **GetLastError** is optional; an application can use the method to determine the specific reason for a failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

CHttpRequest::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** function in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that function for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpQueue::Start Method

```
BOOL Start(  
    DWORD dwQueueMode,  
    HTTPEVENTPROC lpEventProc,  
    DWORD_PTR dwParam  
);
```

The **Start** method begins transferring files in the queue.

Parameters

dwQueueMode

An unsigned integer which specifies which files in the queue should be transferred. It may be one of the following values:

Constant	Description
HTTP_QUEUE_ALL	All files in the queue should be transferred.
HTTP_QUEUE_DOWNLOAD	Transfer only those files which have been queued for download.
HTTP_QUEUE_UPLOAD	Transfer only those files which have been queued for upload.

lpEventProc

Specifies the procedure-instance address of an application defined callback function. For more information about the callback method, see the description of the **HttpEventProc** callback method. If this parameter is NULL, there will be no callback notifications.

dwParam

A user-defined integer value that is passed to the callback method. If the application targets the x86 (32-bit) platform, this parameter must be a 32-bit unsigned integer. If the application targets the x64 (64-bit) platform, this parameter must be a 64-bit unsigned integer.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

Queued file transfers are performed asynchronously using a background worker thread. If you provide the address to an event callback function, that method will always be invoked in the context of the queue manager thread. You must ensure that any access to global or static variables are synchronized, otherwise the results may be unpredictable. It is recommended that you do not declare any static variables within the callback function itself and you should avoid calling any methods which could cause the thread to block. For example, you should not attempt to establish other network connections from within the event handler.

If your application has a graphical user interface, you should never attempt to directly modify a UI control from within the callback method. Controls should only be modified by the same UI thread that created their window. One common approach to address this issue is to post a user-defined message to the main window to signal that the user interface needs to be updated. The message handler would then process the user-defined message and update the user interface as needed.

The callback function specified by the *lpEventProc* parameter must be declared using the **__stdcall** calling convention. This ensures the arguments passed to the event handler are pushed on to the stack in the correct order. Failure to use the correct calling convention will corrupt the stack and cause the application to terminate abnormally.

The *dwParam* parameter is commonly used to identify the class instance which is associated with the event that has occurred. Applications will cast the **this** pointer to a **DWORD_PTR** value when calling this function, and then the event handler will cast it back to a pointer to the class instance. This gives the handler access to the class member variables and methods.

The **Wait** method can be used to wait for the queue manager to complete processing the transfer queue.

Example

```
// Create a new queue
CHttpQueue *pQueue = new CHttpQueue();

// Add a file to the queue
pQueue->AddFile(lpszLocalFile, lpszRemoteFile);

// Start the queued file transfers and wait for it to complete
if (pQueue->Start(HTTP_QUEUE_ALL))
{
    pQueue->Wait(INFINITE);
    pQueue->Stop();
}

// Remove all files from the queue
delete pQueue;
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[CHttpQueue](#), [~CHttpQueue](#), [Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Stop](#), [Suspend](#), [Wait](#)

CHttpQueue::Stop Method

BOOL Stop();

The **Stop** method stops transferring queued files.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

When the **Stop** method is called and there is a file transfer in progress, it will not immediately stop the upload or download of the file. Instead, the queue manager is signaled to stop processing additional files in the queue after the transfer has completed. To wait for the current transfer to complete, call the **Wait** method.

It is permitted to call the **Stop** method from within a queue event handler. In this case, the current file transfer will complete and the queue manager will terminate.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Start](#), [Suspend](#), [Wait](#)

CHttpQueue::Suspend Method

BOOL Suspend();

The **Suspend** method pauses all file transfers for the queue.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero. To get extended error information, call **GetLastError**.

Remarks

If there is a file transfer in progress when this method is called, the transfer will complete normally. The queue manager will enter a suspended state after the transfer has completed and before it begins processing the next file in the queue.

It is permitted to call the **Suspend** method from within a queue event handler. In this case, the current file transfer will complete and the queue manager will stop processing additional files in the queue until it is resumed or stopped.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

See Also

[Cancel](#), [Clear](#), [GetStatus](#), [Resume](#), [Start](#), [Stop](#), [Wait](#)

CHttpQueue::Wait Method

```
BOOL WINAPI HttpWaitForQueue(  
    DWORD dwMilliseconds,  
    LPDWORD lpdwElapsed,  
    LPDWORD lpdwError  
);  
  
BOOL WINAPI HttpWaitForQueue(  
    DWORD dwMilliseconds  
);
```

The **Wait** method waits for the specified queue to complete the file transfers.

Parameters

dwMilliseconds

An unsigned integer value which specifies the number of milliseconds to wait for the queue to complete processing. If this value is zero, the method will return immediately. If this value is INFINITE (0xFFFFFFFF), the method will block indefinitely until all files in the queue have been processed.

lpdwElapsed

A pointer to an unsigned integer which will contain the number of milliseconds the queue manager has been active when the method returns. If this information is not needed, this parameter can be omitted or it can be NULL. If this parameter is not NULL, it will always be initialized to a value of zero.

lpdwError

A pointer to an unsigned integer which will contain the last error code set if a file transfer has failed or was canceled. If this information is not needed, this parameter can be omitted or NULL. If this parameter is not NULL, it will always be initialized to a value of zero.

Return Value

If the method succeeds, the return value is non-zero, which means the queue manager has completed transferring all queued files. If the method fails, or the timeout period elapses, it will return zero. To get extended error information, call **GetLastError**.

Remarks

This method will cause the current thread to block until either the queue manager has completed processing all files in the queue, or until the specified number of milliseconds have elapsed. It is important to note that Windows messages will not be processed during this time. If you call this method within the main UI thread, it can potentially cause the application to become non-responsive. To determine the current state of the queue without blocking the current thread, call the **GetStatus** method.

If the *dwMilliseconds* parameter is non-zero and file transfers have not completed within the specified amount of time, the method will return zero and the last error code will be set to **ST_ERROR_OPERATION_TIMEOUT**.

If an event callback function has been specified when starting the queue, you should never call this method within the event handler. Attempting to do so can potentially create a situation which will cause the application to become non-responsive. The method will return zero if it determines it's being called within the context of the queue manager thread and will set the last error code to **ST_ERROR_THREAD_DEADLOCK**.

Requirements

Hypertext Transfer Queue Data Structures

- HTTPQUEUEDFILE
- HTTPQUEUESTATUS
- HTTPTRANSFERSTATUS
- HTTPTRANSFERSTATUSEX
- SYSTEMTIME

HTTPQUEUEDFILE

This structure is used by the **GetFile**, **GetFirstFile** and **GetNextFile** methods to return information about a file in the transfer queue.

```
typedef struct _HTTPQUEUEDFILE
{
    DWORD          dwFileId;
    DWORD          dwQueueMode;
    DWORD          dwQueueFlags;
    DWORD          dwTimeElapsed;
    DWORD          dwLastError;
    ULARGE_INTEGER uiBytesCopied;
    TCHAR          szLocalFile[HTTP_MAXFILENAMELEN];
    TCHAR          szRemoteFile[HTTP_MAXURLPATHLEN];
} HTTPQUEUEDFILE, *LPHTTPQUEUEDFILE;
```

Members

dwFileId

An unsigned integer which specifies a unique identifier for the queued file. The application should not make any assumptions about the value of the file identifiers. They should be considered opaque values which are only guaranteed to uniquely identify a file in the transfer queue. In particular, there is no guarantee that the file identifiers will be sequential and they should not be used as index values into an array.

dwQueueMode

An unsigned integer value which specifies how the file was queued for transfer. It may be one of the following values:

Constant	Description
HTTP_QUEUE_DOWNLOAD	The file was queued for download.
HTTP_QUEUE_UPLOAD	The file was queued for upload.

dwQueueFlags

An unsigned integer which specifies one or more bit flags which provides information about the status of the file transfer. It may be one or more of the following values:

Constant	Description
HTTP_QUEUE_FLAG_NONE	The file is pending transfer in queue.
HTTP_QUEUE_FLAG_COMPLETED	The file has been transferred successfully. If this flag is set, no errors were encountered during the upload or download.
HTTP_QUEUE_FLAG_FAILED	The file transfer failed. If this flag is set, the <i>dwError</i> member of this structure will contain the error code associated with the failed transfer.
HTTP_QUEUE_FLAG_CANCELED	The file transfer was canceled. This flag is only set when the Cancel method has been called and a queued file is in the process of being uploaded or downloaded.

dwTimeElapsed

An unsigned integer which specifies the number of milliseconds required to complete the transfer. This value will be zero unless the file has been transferred successfully.

dwLastError

An unsigned integer which specifies the last error code for a failed transfer. If the file was transferred successfully, this value will be zero.

uiBytesCopied

A value which specifies the number of bytes which were copied during the file transfer. The ULARGE_INTEGER type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

szLocalFile

A null terminated string which specifies the full path to the local file being transferred.

szRemoteFile

A null terminated string which specifies the complete URL to the remote file being transferred.

Remarks

It is possible that the ***szLocalFile*** and ***szRemoteFile*** structure members will be different than the values passed to the **AddFile** method. Those values are normalized, with any relative paths converted to absolute paths. Internationalized domain names will be encoded and the URL paths will be collapsed, removing any extraneous path information. For example, if the remote file name is specified as **http://http.server.tld/folder1/./folder2/filename.txt** it would be normalized as **http://http.server.tld/folder2/filename.txt**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshttpv11.lib

Unicode: Implemented as Unicode and ANSI versions

HTTPQUEUESTATUS

This structure is used by the **GetStatus** method to return information about the current status of the file transfer queue.

```
typedef struct _HTTPQUEUESTATUS
{
    DWORD dwStatus;
    DWORD dwThreadId;
    DWORD dwQueuedFiles;
    DWORD dwPendingFiles;
    DWORD dwCopiedFiles;
    DWORD dwFailedFiles;
    DWORD dwTimeElapsed;
    DWORD dwCurrentFile;
    DWORD dwLastError;
    ULARGE_INTEGER uiBytesCopied;
    ULARGE_INTEGER uiBytesTotal;
} HTTPQUEUESTATUS, *LPHTTPQUEUESTATUS;
```

Members

dwStatus

An unsigned integer which specifies the current status of the queue. It can be one of the following values:

Value	Description
HTTP_QUEUE_STATUS_IDLE	The file transfer queue is idle and no files are being uploaded or downloaded. This state is returned before the Start method has been called or after the Stop method has been called. The queue will also automatically enter an idle state after the last file transfer has completed and the queue manager thread exits.
HTTP_QUEUE_STATUS_ACTIVE	Files in the queue are being uploaded or downloaded. The <i>dwCurrentFile</i> member of this structure identifies the file which is currently being transferred.
HTTP_QUEUE_STATUS_PAUSED	File transfers are currently paused. The queue enters this state after the Suspend method is called and resumes file transfers after the Resume method is called.

dwThreadId

An unsigned integer which specifies the thread ID for the queue manager which is performing the file transfers. All file transfers are performed asynchronously in a background worker thread. If this structure member is zero, the queue is idle and not performing file transfers. The application should not use the thread ID to obtain a handle to suspend or terminate the thread. This can potentially result in unexpected behavior or instability within the application.

dwQueuedFiles

An unsigned integer which specifies the total number of queued files. This value includes pending and completed file transfers.

dwPendingFiles

An unsigned integer which specifies the number of files which are queued to be transferred.

dwCopiedFiles

An unsigned integer which specifies the number of files which have been successfully transferred. This value reflects the total number of files which have the HTTP_QUEUE_FLAG_COMPLETED status.

dwFailedFiles

An unsigned integer which specifies the number of files which have failed to transfer or the file transfer has been canceled. This value reflects the total number of files which have the HTTP_QUEUE_FLAG_FAILED status.

dwTimeElapsed

An unsigned integer which specifies the total amount of time, in milliseconds, the queue manager has been active performing a file transfer. If the queue is idle, this value will reflect the total run time for the previously active queue. A value of zero indicates the queue was never active or the queue state has been reset with a call to the **Reset** method.

dwCurrentFile

An unsigned integer which specifies the unique identifier for the current file being transferred. If no file transfer is in progress, this member will have a value of zero. If the value is non-zero, it can be passed to the **GetFile** method to obtain information about the queued file.

dwLastError

An unsigned integer which specifies the last error code for a failed file transfer. If there have been no errors, this value will be zero.

uiBytesCopied

A value which specifies the number of bytes which were copied during the current or last transfer. The ULARGE_INTEGER type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

uiBytesTotal

A value which specifies the total number of bytes which were copied during the current queue run. The ULARGE_INTEGER type is a union of a structure and a 64-bit value which can be used on both 32-bit and 64-bit systems. For languages other than C/C++ you can define this structure member as an unsigned 64-bit integer type.

HTTPTRANSFERSTATUS

This structure is used by the **GetTransferStatus** method to return information about a data transfer in progress.

```
typedef struct _HTTPTRANSFERSTATUS
{
    DWORD    dwBytesTotal;
    DWORD    dwBytesCopied;
    DWORD    dwBytesPerSecond;
    DWORD    dwTimeElapsed;
    DWORD    dwTimeEstimated;
} HTTPTRANSFERSTATUS, *LPHTTPTRANSFERSTATUS;
```

Members

dwBytesTotal

The total number of bytes that will be transferred. If the data is being downloaded from the server to the local host, this is the size of the requested resource. If the data is being uploaded from the local host to the server, it is the size of the local file or memory buffer. If the size of the resource cannot be determined, this value will be zero.

dwBytesCopied

The total number of bytes that have been copied.

dwBytesPerSecond

The average number of bytes that have been copied per second.

dwTimeElapsed

The number of seconds that have elapsed since the file transfer started.

dwTimeEstimated

The estimated number of seconds until the data transfer is completed. This is based on the average number of bytes transferred per second.

Remarks

If the option HTTP_OPTION_HIRES_TIMER has been specified when connecting to the server, the values returned in the *dwTimeElapsed* and *dwTimeEstimated* members will be in milliseconds instead of seconds. You can use this option to obtain more accurate elapsed times when uploading or downloading small amounts of data over a fast network connection.

Library Information

File Name	CSHTSV11.DLL
Version	11.0.2218.1855
LibID	475FBDFE-E206-4E5A-93E0-D69A7FC2E858
Import Library	CSHTSV11.LIB
Dependencies	None
Standards	RFC 1945, RFC 2616, RFC 3875

Overview

This library provides an interface for implementing an embedded, lightweight server that can be used to provide access to documents and other resources using the standard Hypertext Transfer Protocol. The server can accept connections from any standard web browser, third-party applications or programs developed using the SocketTools HTTP client API.

The application specifies an initial server configuration and then responds to events that are generated when the client sends a request to the server. An application may implement only minimal handlers for most events, in which case the default actions are performed for most standard HTTP commands. However, an application may also use the event mechanism to filter specific commands or to extend the protocol by providing custom implementations of existing commands or add entirely new commands.

The server includes support for CGI scripting, virtual hosting, client authentication and the creation of virtual directories and files. The server also supports secure connections using TLS. Secure connections require a valid security certificate to be installed on the system.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical

updates available for your version of the operating system.

This class provides an implementation of a multithreaded server which should only be used with languages that support the creation of multithreaded applications. It is important that you do not attempt to link against static libraries which were not built with support for threading.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

CHttpServer Public Data Members

Member Variables	Description
m_nCacheTime	The number of seconds until the client should consider a cached response to be stale
m_nExecTime	The maximum number of seconds that the server will permit an external command to execute
m_nIdleTime	The maximum number of seconds a client can be idle before the server terminates the session
m_nLogFormat	The format used by the server to log client activity
m_nLogLevel	The level of detail included in the server log file
m_nMaxClients	The maximum number of active client sessions accepted by the server
m_nMaxClientsPerAddress	The maximum number of clients per IP address accepted by the server
m_nMaxPostSize	The maximum amount of data a client may submit to the server
m_nMaxRequests	The maximum number of requests a client may make per connection
m_dwOptions	Options specified when creating an instance of the server
m_dwStackSize	The initial size of the stack allocated for threads created by the server

CHttpRequest::m_nExecTime

UINT m_nExecTime;

The maximum number of seconds that the server will permit an external command to execute.

Remarks

The **m_nExecTime** data member is a public variable that specifies the maximum number of seconds that an external CGI program is permitted to run on the server. Programs are registered using the **RegisterProgram** method and are executed when the client sends a request for a resource that is associated with the program. If this value is zero, the default timeout period of 5 seconds will be used. The minimum execution time is 1 second and the maximum time limit is 30 seconds. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CHttpServer](#), [RegisterProgram](#)

CHttpServer::m_nIdleTime

UINT m_nIdleTime;

The maximum number of seconds a client can be idle before the server terminates the session.

Remarks

The **m_nIdleTime** data member is a public variable that specifies the maximum number of seconds that a client session may be idle before the server closes the control connection to the client. A value of zero specifies the default value of 60 seconds. If the value is non-zero, the minimum value is 10 seconds and the maximum value is 300 seconds (5 minutes). This value is used to initialize the default idle timeout period for each client session. The server determines if a client is idle based on the time the last command was issued and whether or not a file transfer is in progress. Changing the value of this data member does not have an effect on an active instance of the server.

See Also

[CHttpServer](#), [RegisterProgram](#), [SetClientIdleTime](#)

CHttpServer::m_nLogFormat

UINT m_nLogFormat;

The format used when updating the server log file.

Remarks

The **m_nLogFormat** data member is a public variable that specifies the format of the log file that is created or updated by the server. It may be one of the following values:

Value	Description
HTTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
HTTP_LOGFILE_COMMON	This value specifies that the log file should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about file transfers.
HTTP_LOGFILE_COMBINED	This value specifies that the server should use the combined log file format. This format is similar to the common format, however it includes the client referrer and user agent. This is the format that most Apache web servers use by default.
HTTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session.

By default, logging is not enabled for the server. Changing the value of this data member does not have an effect on an active instance of the server. To change the format, level of detail or default log file name, use the **SetLogFile** method.

See Also

[CHttpServer](#), [GetLogFile](#), [SetLogFile](#)

CHttpServer::m_nLogLevel

UINT m_nLogLevel;

The level of detail included in the server log file.

Remarks

The **m_nLogLevel** data member is a public variable that specifies the level of detail that should be generated in the log file. The minimum value is 1 and the maximum value is 10. If the **m_nLogFormat** data member specifies a valid log file format and this value is zero, a default level of detail will be selected based on the format.

The common log file format generally contains less information by default, only logging the data transfers between the client and server. The W3C extended log file format defaults to a higher level of detail that includes additional information about the client session. The higher the level of detail, the larger the log file will be.

By default, logging is not enabled for the server. Changing the value of this data member does not have an effect on an active instance of the server. To change the format, level of detail or default log file name, use the **SetLogFile** method.

See Also

[CHttpServer](#), [GetLogFile](#), [SetLogFile](#)

CHttpServer::m_nMaxClients

`UINT m_nMaxClients;`

The maximum number of clients that are permitted to connect to the server.

Remarks

The **m_nMaxClients** data member is a public variable that specifies the maximum number of clients that are permitted to establish a connection with the server. After this limit is reached, the server will reject additional connections until the number of active clients drops below this threshold. A value of zero specifies that there is no fixed limit on the active number of client connections. Changing the value of this data member does not have an effect on an active instance of the server. To change the maximum number of clients on an active server, use the **Throttle** method.

The actual number of client connections that can be accepted depends on the amount of memory available to the server process. Sockets are allocated from the non-paged memory pool, so the actual number of sockets that can be created system-wide depends on the amount of physical memory that is installed. If the server will be accessible over the Internet, it is recommended that you limit the maximum number of client connections to a reasonable value.

See Also

[CHttpServer](#), [Throttle](#)

CHttpServer::m_nMaxClientsPerAddress

UINT m_nMaxClientsPerAddress;

The maximum number of clients that are permitted to connect to the server from a single IP address.

Remarks

The **m_nMaxClientsPerAddress** data member is a public variable that specifies the maximum number of clients that are permitted to establish a connection with the server from a single IP address. After this limit is reached, the server will reject additional connections until the number of active clients drops below this threshold. A value of zero specifies that there is no limit on the active number of client connections per IP address. Changing the value of this data member does not have an effect on an active instance of the server. To change the maximum number of clients on an active server, use the **Throttle** method.

It is not recommended that you set the maximum clients per address below a value of 4. Lower values can negatively impact the performance of some clients, and may result in unexpected errors.

See Also

[CHttpServer](#), [Throttle](#)

CHttpServer::m_dwOptions

DWORD m_dwOptions;

The default options used when starting an instance of the server.

Remarks

The **m_dwOptions** data member is a public variable that specifies the default options that should be used when starting an instance of the server. This variable can be modified directly or by calling the **SetOptions** method. For a list of available server options, see [Server Option Constants](#). Changing the value of this data member does not have an effect on an active instance of the server.

CHttpServer Methods

Class	Description
CHttpServer	Constructor which initializes the current instance of the class
~CHttpServer	Destructor which releases resources allocated by the class
Method	Description
AddVirtualHost	Add a new virtual host to the server virtual host table
AddVirtualHostAlias	Add an alternate host name for an existing virtual host
AddVirtualPath	Add a new virtual path for the specified host
AddVirtualUser	Add a new virtual user for the specified host
AsyncNotify	Enable or disable asynchronous notification of changes in server status
AttachHandle	Attach the specified server handle to this instance of the class
AuthenticateClient	Authenticate the client and assign access rights for the session
CheckVirtualPath	Determine if the client has permission to access the specified virtual path
DeleteAllClientHeaders	Delete all of the request or response headers for the specified client session
DeleteClientHeader	Delete a request or response header for the specified client session
DeleteVirtualHost	Delete a virtual host associated with the specified server
DeleteVirtualPath	Remove a virtual path from the specified host
DeleteVirtualUser	Delete a virtual user from the specified host
DetachHandle	Detach the server handle from the current instance of this class
DisableCommand	Disable a specific server command
DisableTrace	Disable the logging of network function calls
DisconnectClient	Disconnect the specific client session, closing the control channel and aborting any file transfer
EnableClientAccess	Enable or disable access rights for the specified client session
EnableCommand	Enable a specific server command
EnableTrace	Enable logging of network function calls to a file
EnumClients	Returns a list of active client connections established with the server
GetActiveClient	Return the client ID for the active client session associated with the current thread
GetAddress	Return the IP address for the server
GetAllClientHeaders	Return all client request or response headers in a string buffer
GetClientAccess	Return the access rights that have been granted to the client session
GetClientAddress	Return the IP address of the specified client session
GetClientCredentials	Return the credentials for the specified client session
GetClientDirectory	Return the root document directory for a client session

GetClientHeader	Return the value of a request or response header for the specified client session
GetClientIdleTime	Return the idle timeout period for the specified client
GetClientLocalPath	Return the full local path for the specified virtual path
GetClientServer	Return the handle to the server that created the specified client session
GetClientThreadId	Returns the thread ID associated with the specified client session
GetClientUserName	Return the user name associated with the specified client session
GetClientVariable	Return the value of a CGI environment variable for the specified client
GetClientVirtualHost	Return the name of the virtual host the client used to establish the connection
GetClientVirtualHostId	Return the virtual host ID associated with the specified client session
GetClientVirtualPath	Return the virtual path for a local file on the server
GetCommandFile	Return the full path to the local file name or directory specified by the client
GetCommandLine	Return the complete command line issued by the client
GetCommandName	Return the name of the command that was issued by the client
GetCommandQuery	Return the query parameters included with the command
GetCommandResource	Return the path for the resource requested by the client
GetCommandResult	Return the result code and a description of the last command processed by the server
GetCommandUrl	Return the complete URL of the resource requested by the client
GetDirectory	Return the full path to the root directory assigned to the specified server
GetHandle	Return the server handle associated with the class instance
GetIdentity	Return the identity and version information for the specified server
GetLastError	Return information about the last server error that occurred
GetLogFile	Return the current log file format and full path for the file
GetMemoryUsage	Return the amount of memory allocated for the server and all client sessions
GetName	Return the host name assigned to the server or specified client session
GetOptions	Return the options specified for this instance of the server
GetPriority	Return the current priority assigned to the specified server
GetProgramExitCode	Return the exit code of the last program executed by the client
GetProgramName	Return the name of the CGI program executed by the client
GetProgramOutput	Return a copy of the standard output from the last program executed by the client
GetProgramText	Return a copy of the standard output from the last program in a string buffer
GetStackSize	Return the initial size of the stack allocated for threads created by the server
GetTransferInfo	Return information about the current file transfer
GetUuid	Return the UUID assigned to the specified server
GetVirtualHostId	Return the virtual host ID associated with the specified hostname

GetVirtualHostName	Return the hostname associated with the specified virtual host ID
IsActive	Determine if the server has been started
IsClientAuthenticated	Determine if the specified client session has been authenticated
IsCommandEnabled	Determine if the specified command is currently enabled or disabled
IsInitialized	Determine if the class has been successfully initialized
IsListening	Determine if the server is listening for client connections
PreProcessEvent	Filter server events before being processed by the default event handler
ReceiveRequest	Receive the request that was sent by the client to the server
RedirectRequest	Redirect the request from the client to another URL
RegisterHandler	Register a CGI program for use and associate it with a file name extension
RegisterProgram	Register a CGI program for use and associate it with a virtual path on the server
RenameServerLogFile	Rename or delete the current log file being updated by the server
RequireAuthentication	Send a response to the client indicating that authentication is required
Restart	Restart the server, terminating all active client sessions
Resume	Resume accepting client connections on the specified server
SendErrorResponse	Send a customized error response to the specified client
SendResponse	Send a response from the server to the specified client
SendResponseData	Send additional data to the client in response to a command
SetCertificate	Set the name of the certificate to be used with secure connections.
SetClientAccess	Change the access rights associated with the specified client session
SetClientHeader	Create or change the value of a request or response header for the client session
SetClientIdleTime	Change the idle timeout period for the specified client session
SetClientVariable	Create or change the value of a CGI environment variable for the specified client
SetCommandFile	Change the name of the local file or directory that is the target of the current command
SetDirectory	Specify the local directory that will be used as the server root directory
SetLastError	Set the last error code for the specified server session
SetLogFile	Change the current log format, level of detail and file name
SetIdentity	Change the identity and version information for the specified server
SetName	Change the hostname assigned to the server or specified client session
SetOptions	Change the options specified for this instance of the server
SetPriority	Change the priority assigned to the specified server
SetStackSize	Change the initial size of the stack allocated for threads created by the server
SetUuid	Assign a UUID to be associated with this instance of the server
Start	Start the server and begin accepting client connections

Stop	Stop the server and terminate all active client connections
Suspend	Suspend accepting client connections on the specified server
Throttle	Limit the number of active client connections, connections per address and connection rate

CHttpServer::~CHttpServer

~CHttpServer();

The **CHttpServer** destructor releases resources allocated by the current instance of the **CHttpServer** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CHttpServer** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CHttpServer](#)

CHttpServer::AddVirtualHost Method

```
UINT HttpAddVirtualHost(  
    LPCTSTR lpszHostName,  
    UINT nHostPort,  
    LPCTSTR lpszDirectory  
);
```

Add a new virtual host to the server virtual host table.

Parameters

lpszHostName

A pointer to a string which specifies the hostname that will be added to the virtual host table. This parameter must specify a valid hostname and cannot be a NULL pointer or a zero-length string.

nHostPort

An integer value which specifies the port number for the virtual host. This value must be zero or the same value as the original port number that the server was configured to use.

lpszDirectory

A pointer to a NULL terminated string which specifies the root document directory for the virtual host. If this parameter is NULL or a zero-length string, the virtual host will use the same root directory that was specified when the server was started. This parameter may contain environment variables enclosed in % symbols.

Return Value

If the method is successful, it will return a non-zero integer value that identifies the virtual host. If the method fails, it will return INVALID_VIRTUAL_HOST and the last error code will be updated to indicate the cause of the failure.

Remarks

Virtual hosting is a method for sharing multiple domain names on a single instance of a server. The client provides the server with the hostname that it has used to establish the connection, and that name is compared against a table of virtual hosts configured for the server. If the hostname matches a virtual host, the client will use the root directory and any virtual paths that have been assigned to that host.

When the server is first started, a default virtual host with an ID of zero is automatically created and is identified as VIRTUAL_HOST_DEFAULT. This virtual host uses the same hostname, port number and root directory that the server instance was created with. The application should treat all other host IDs as opaque values and never make assumptions about how they are allocated.

The *nHostPort* parameter should always be specified with a value of zero, or the same port number that the server was configured to use. Port-based virtual hosting is currently not supported and this parameter is included for future use.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddVirtualHostAlias](#), [AddVirtualPath](#), [DeleteVirtualHost](#), [GetVirtualHostId](#), [GetVirtualHostName](#)

CHttpServer::AddVirtualHostAlias Function

```
BOOL AddVirtualHostAlias(  
    UINT nHostId,  
    LPCTSTR lpszHostAlias  
);  
BOOL AddVirtualHostAlias(  
    LPCTSTR lpszHostAlias  
);
```

Add an alternate host name for an existing virtual host.

Parameters

nHostId

An integer value which identifies the virtual host. If this parameter is omitted, the alias will be assigned to the default server.

lpszHostAlias

A pointer to a string which specifies the alias for the virtual host. The alias must be a valid domain name that uniquely identifies the host. This parameter cannot be a NULL pointer or specify an empty string.

Return Value

If the function succeeds, the return value is non-zero. If the virtual host ID does not specify a valid host, the function will return zero. If the function fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **AddVirtualHostAlias** method adds an alias for an existing virtual host. This enables a client to establish a connection using a number of different domain names which all reference the same virtual host. When the server responds to the client, it will identify itself with the primary domain name assigned to the virtual host rather than the alias provided by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddVirtualHost](#), [AddVirtualPath](#)

CHttpServer::AddVirtualPath Function

```
BOOL AddVirtualPath(  
    UINT nHostId,  
    LPCTSTR lpszVirtualPath,  
    LPCTSTR lpszLocalPath,  
    DWORD dwFileAccess  
);
```

Add a new virtual path for the specified host.

Parameters

nHostId

An integer value which identifies the virtual host. If this parameter is omitted, the default virtual host will be used.

lpszVirtualPath

A pointer to a string which specifies the virtual path that will be created. This parameter cannot be a NULL pointer or an empty string. The maximum length of the virtual path is 1024 characters.

lpszLocalPath

A pointer to a string which specifies the local directory or file name that the virtual path will be mapped to. This path must exist and can be no longer than MAX_PATH characters. This parameter cannot be a NULL pointer or an empty string.

dwFileAccess

An integer value which specifies the access clients will be given to the virtual path. For a list of file access permissions, see [User and File Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the virtual host ID does not specify a valid host, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **AddVirtualPath** method maps a virtual path name to a directory or file name on the local system. Virtual paths are assigned to specific hosts and if multiple virtual hosts are created for the server, each can have its own virtual paths which map to different files. To create a virtual path for the default server, the *nHostId* parameter should be specified as VIRTUAL_HOST_DEFAULT.

It is recommended that the *lpszLocalPath* parameter always specify the full path to the local file or directory. If the path is relative, it will be considered relative to the current working directory for the process and expanded to its full path name. The local path can include environment variables surrounded by % symbols. For example, if the value %ProgramData% is included in the path, it will be expanded to the full path for the common application data folder. The local path cannot specify a Windows system folder or the root directory of a mounted drive volume.

The local file or directory does not need to be located in the document root directory for the server or virtual host. It can specify any valid local path that the server process has the appropriate permissions to access. You should exercise caution when creating virtual paths to files or directories outside of the server root directory. If the *lpszLocalPath* parameter specifies a directory, clients will have access to that directory and all subdirectories using its virtual path.

If you wish to password protect the virtual file or directory, include the HTTP_ACCESS_PROTECTED

flag in the file permissions. The default command handlers will recognize this flag and require that the client authenticate itself to grant access to the resource. If the server application implements a custom command handler, it is responsible for checking for the presence of this flag and perform the appropriate checks to ensure that the client session has been authenticated.

If the server was started in restricted mode, the client will be unable to access documents outside of the server root directory and its subdirectories. This restriction also applies to virtual paths that reference documents or other resources outside of the root directory. To allow a client to access a document outside of the server root directory, the **SetClientAccess** method should be used to grant the client HTTP_ACCESS_READ permission.

The **GetClientVirtualPath** method will return the virtual path that is associated with a local file or directory. The **GetClientLocalPath** method will return the full path to a local file or directory that is mapped to a virtual path.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::AddVirtualUser Method

```
BOOL AddVirtualUser(  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    DWORD dwUserAccess,  
    LPCTSTR lpszDirectory  
);
```

```
BOOL AddVirtualUser(  
    UINT nHostId,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword,  
    DWORD dwUserAccess,  
    LPCTSTR lpszDirectory  
);
```

Add a new virtual user for the specified host.

Parameters

nHostId

An integer value which identifies the virtual host. If this parameter is omitted, the default virtual host will be used.

lpszUserName

A pointer to a string which specifies the user name. The maximum length of a username is 63 characters and it is recommended that names be limited to alphanumeric characters. Whitespace, control characters and certain symbols such as path delimiters and wildcard characters are not permitted. If an invalid character is included in the name, the method will fail with an error indicating the username is invalid. This parameter cannot be NULL and the name must be at least three characters in length. Usernames are not case sensitive.

lpszPassword

A pointer to a string which specifies the user password. The maximum length of a password is 63 characters and is limited to printable characters. Whitespace and control characters are not permitted. If an invalid character is included in the password, the method will fail with an error indicating the password is invalid. This parameter cannot be NULL and must be at least one character in length. Passwords are case sensitive.

dwUserAccess

An integer value which specifies the access clients will be given when authenticated as this user. For a list of user access permissions, see [User and File Access Constants](#). If this parameter is omitted, default access rights will be assigned based on the server configuration.

lpszDirectory

A pointer to a string which specifies the local directory that is considered to be the virtual user's home directory. This path must exist and can be no longer than MAX_PATH characters. The maximum length of the local path is 260 characters. The directory cannot be located in a Windows system folder or the root directory of a mounted disk volume. If this parameter is omitted, the server root directory will be assigned as the user home directory.

Return Value

If the method succeeds, the return value is non-zero. If the the virtual host ID does not specify a valid host, or the username or password contain invalid characters, the method will return zero. If the

method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **AddVirtualUser** method adds a virtual user that is associated with the specified virtual host. If a client attempts to access a protected document and provides credentials, the server will attempt to automatically authenticate the session by searching for virtual user with the same username and password. If a match is found, then the client session is assigned the same access permissions as the virtual user.

If the server is started with the HTTP_SERVER_MULTUSER option, then documents in the virtual user's home directory can be accessed by specifying their username using a specially formatted request URL. For example, if a virtual user named "Thomas" is created, the documents in that user's home directory could be accessed as `http://servername/~thomas/document.html`

All files and subdirectories in the user's home directory are considered to be read-only. A client cannot create files in a user's home directory, even if they are authenticated as that user. In addition, CGI programs and scripts cannot be executed from a user's home directory.

If you wish to modify the information for a user, it is not necessary to delete the username first. If this method is called with a username that already exists, that record is replaced with the values passed to this method.

The virtual users created by this method exist only as long as the server is active. If you wish to maintain a persistent database of users and passwords, you are responsible for its implementation based on the requirements of your specific application. For example, a simple implementation would be to store the user information in a local XML or INI file and then read that configuration file after the server has started, calling this method for each user that is listed.

Requirements

[AddVirtualHost](#), [DeleteVirtualUser](#)

CHttpServer::AsyncNotify Method

```
BOOL AsyncNotify(  
    HWND hWnd,  
    UINT uMsg  
);
```

Enable or disable asynchronous notification of changes in server status.

Parameters

- hWnd**
A handle to the window whose window procedure will receive the notification message.
- uMsg**
The user-defined message that will be sent to the notification window.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **AsyncNotify** method is used by an application to enable or disable asynchronous notifications. The message window is typically the main UI window and these notifications are used signal to the application that it should update the user interface. If the **hWnd** parameter is not NULL, it must specify a valid window handle and the user-defined message must have a value of **WM_USER** or higher. The application cannot specify a notification message that is reserved by the operating system. The pseudo-handle **HWND_BROADCAST** cannot be specified as the notification window. If the **hWnd** parameter is NULL, notifications for the specified server will be disabled.

When asynchronous notifications are enabled for a server, the server will post the user-defined message to the window whenever there is a change in status or after a client has connected or disconnected from the server. The **wParam** message parameter will contain the notification message and the **lParam** message parameter will contain the handle to the server or the client ID. The following notification messages are defined:

Value	Description
HTTP_NOTIFY_STARTUP	This notification is sent when the server has started and is preparing to accept client connections. This notification is only sent once, and only if asynchronous notifications are enabled immediately after the Start method is called. This message will not be sent once the server has begun accepting client connections or when notification messages are disabled and then subsequently re-enabled at a later time. The lParam message parameter will specify the handle to the server.
HTTP_NOTIFY_LISTEN	This notification is sent when the server is listening for client connections. This notification message may be sent to the application multiple times over the lifetime of the server. If the server was suspended, this notification will be sent after the application calls the Resume method to resume accepting client connections. The lParam message

	parameter will specify the handle to the server.
HTTP_NOTIFY_SUSPEND	This notification is sent when the server suspends accepting new connections because the application has called the Suspend method. This notification message may be sent to the application multiple times over the lifetime of the server. The <i>lParam</i> message parameter will specify the handle to the server.
HTTP_NOTIFY_RESTART	This notification is sent when the server is restarted using the Restart method. Note that the server socket handle provided by the <i>lParam</i> message parameter will specify the new socket handle of the restarted server instance, not the original socket handle. The <i>lParam</i> message parameter will specify the handle to the server.
HTTP_NOTIFY_CONNECT	This notification is sent when the server accepts a client connection and the thread that manages the client session has begun processing network events for that client. This message notification will not be sent if the client connection is rejected by the server. The <i>lParam</i> message parameter will specify the unique ID of the client that connected to the server.
HTTP_NOTIFY_DISCONNECT	This notification is sent when the client disconnects from the server and the client socket has been closed. This notification message may not occur for each client session that is forced to terminate as the result of the server being stopped using the Stop method. The <i>lParam</i> message parameter will specify the unique ID of the client that disconnected from the server.
HTTP_NOTIFY_SHUTDOWN	This notification is sent when the server thread is in the process of terminating. At the time the application processes this notification message, the server handle in <i>lParam</i> will reference the defunct server and cannot be used with other server methods. The <i>lParam</i> message parameter will specify the handle to the server.

If asynchronous notifications are enabled, you should never use those notifications as a replacement for an event handler. When an event occurs, the callback function that handles the event is invoked in the context of the thread that manages the client session. The application should exchange data with the client within that event handler and not in response to a notification message. These notification messages should only be used to update the application UI in response to changes in the status of the server.

The HTTP_NOTIFY_CONNECT and HTTP_NOTIFY_DISCONNECT notifications are different from the other server notifications because the *lParam* message parameter does not specify the server handle, but rather the unique client ID associated with the session that connected to or disconnected from the server. Use the **GetClientServer** method to obtain a handle to the server that created the client session. Note that at the time the application processes the HTTP_NOTIFY_DISCONNECT notification message, the client session will have already terminated.

CHttpServer::AttachHandle Method

```
VOID AttachHandle(  
    HSERVER hServer  
);
```

The **AttachHandle** method attaches the specified server handle to the current instance of the class.

Parameters

hServer

The handle to the server that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a server handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that server.

If a server handle already has been created for the class, that handle will be released when the new handle is attached to the class object. This will cause the server to stop and all client sessions will be terminated immediately. If you want to prevent the previous server from being stopped, you must call the **DetachHandle** method prior to attaching a new handle to the class instance.

Note that the *hServer* parameter is presumed to be a valid server handle and no checks are performed to ensure that the handle references an active server. Specifying an invalid server handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[DetachHandle](#), [GetHandle](#)

CHttpServer::AuthenticateClient Method

```
BOOL AuthenticateClient(  
    UINT nClientId,  
    DWORD dwUserAccess  
);
```

Authenticate the client and assign access rights for the session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more user access rights. For a list of user access rights that can be granted to the client, see [User and File Access Constants](#).

Return Value

If the the client session could be authenticated, the return value is non-zero. If the client ID does not specify a valid client session, or the client has already been authenticated, this method will return zero.

Remarks

The **HttpAuthenticateClient** method is used to authenticate a specific client session, typically in response to an **OnAuthenticate** event that indicates a client has provided authentication credentials as part of the request for a document or other resource.

To enable the server to automatically authenticate a client session, use the **AddVirtualUser** method to add one or more virtual users. The server will search the list of virtual users for a match to the credentials provided by the client and will set the appropriate permissions for the session without requiring a event handler to manually authenticate the session using this method.

If the server was started with the HTTP_SERVER_LOCALUSER option and the client session is not authenticated using this method, the server will attempt to authenticate the client session using the local Windows user database. Although this option can be convenient because it does not require the implementation of an event handler for the **OnAuthenticate** event, it can be used by clients to attempt to discover valid usernames and passwords for the local system. It is recommended that you use the **AddVirtualUser** method to create virtual users rather than using the local user database.

It is recommended that most applications specify HTTP_ACCESS_DEFAULT as the *dwUserAccess* value for a client session, since this allows the server automatically grant the appropriate access based on the server configuration options.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AddVirtualUser](#), [GetClientCredentials](#), [GetClientDirectory](#), [OnAuthenticate](#)

CHttpServer::CheckVirtualPath Method

```
BOOL CheckVirtualPath(  
    UINT nClientId,  
    LPCTSTR lpszVirtualPath,  
    DWORD dwFileAccess  
);
```

Determine if the client has permission to access the specified virtual path.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszVirtualPath

A pointer to a string which specifies the virtual path that should be checked. This path must be absolute and cannot be a NULL pointer or an empty string. The maximum length of the virtual path is 1024 characters.

dwFileAccess

An unsigned integer value which specifies the access permissions that should be checked. For a list of file access permissions, see [User and File Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **CheckVirtualPath** method is used to determine if the client has permission to access the virtual file or directory, based on the value of the *dwFileAccess* parameter. For example, if the *dwFileAccess* parameter has the value HTTP_ACCESS_WRITE, this method will check if the client has write permission for the file or directory. The method will return a non-zero value if the client does have the requested permission, or zero if it does not.

Applications that implement their own custom handlers for standard HTTP commands should use this method to ensure that the client has the appropriate permissions to access the requested resource. Failure to check the access permissions for the client can result in the client being able to access restricted documents and other resources. It is recommended that most applications use the default command handlers.

To obtain the path to the local file or directory that the virtual path is mapped to, use the **GetClientLocalPath** method.

Example

```
CString strPathName;  
  
// Get the current request URL path  
INT cchPathName = pServer->GetCommandResource(nClientId, strPathName);  
  
if (cchPathName == 0)  
{  
    pServer->SendErrorResponse(nClientId, 500);  
    return;  
}
```

```
}

// Check if the client has write access to that resource
BOOL bAllowed = pServer->CheckVirtualPath(
    nClientId,
    strPathName,
    HTTP_ACCESS_WRITE);

if (!bAllowed)
{
    pServer->SendErrorResponse(nClientId, 403);
    return;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[AddVirtualPath](#), [DeleteVirtualPath](#), [GetClientLocalPath](#), [GetClientVirtualPath](#)

CHttpServer::CHttpServer Method

CHttpServer();

The **CHttpServer** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **HttpServerInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** method because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[~CHttpServer](#), [IsInitialized](#)

CHttpServer::DeleteAllClientHeaders Method

```
BOOL DeleteAllClientHeaders(  
    UINT nClientId,  
    UINT nHeaderType  
);
```

Delete all of the request or response headers for the specified client session.

Parameters

nClientId

Delete all of the request or response headers for the specified client session.

nHeaderType

Specifies the type of headers to delete. It may be one of the following values:

Value	Description
HTTP_HEADERS_REQUEST	Delete all of the request headers that were provided by the client. Request header values provide additional information to the server about the type of request being made.
HTTP_HEADERS_RESPONSE	Delete all of the response headers that were created by the server in response to a request made by the client. Response header values provide additional information to the client about the type of information that is being returned by the server.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **DeleteAllClientHeaders** method is used to delete all of the request or response headers that were set as the result of the client issuing a request for a document or other resource. If this method is used to delete all of the response headers, the server will automatically generate a standard set of response headers when it returns the requested information to the client.

It is not necessary to call this method inside an **OnDisconnect** event handler to delete the header values that were set during the client session. This is done automatically when the client disconnects from the server.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** cshtsv11.lib

See Also

[DeleteClientHeader](#), [SetClientHeader](#)

CHttpServer::DeleteClientHeader Function

```
BOOL DeleteClientHeader(  
    UINT nClientId,  
    UINT nHeaderType,  
    LPCTSTR LpszHeaderName  
);
```

Delete a request or response header for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nHeaderType

Specifies the type of header to delete. It may be one of the following values:

Value	Description
HTTP_HEADERS_REQUEST	Delete a request header that was provided by the client. Request header values provide additional information to the server about the type of request being made.
HTTP_HEADERS_RESPONSE	Delete a response header that was created by the server. Response header values provide additional information to the client about the type of information that is being returned by the server.

lpszHeaderName

A pointer to a string that specifies the name of the header that should be deleted. Header names are not case-sensitive and should not include the colon which acts as a delimiter that separates the header name from its value. This parameter cannot be a NULL pointer or an empty string.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **DeleteClientHeader** method will delete a request or response header for the specified client session. There are a number of required response headers that are always sent to a client and deleting the header using this method will cause the server to automatically generate a new default header value. You should not delete response header values unless you are certain of the impact that it would have on the normal operation of the client.

It is not necessary for you to delete a header value to change the value of an existing header. The **SetClientHeader** method will replace an existing header value with a new value, or create a new header if the header name does not already exist.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::DeleteVirtualHost Method

```
BOOL DeleteVirtualHost(  
    UINT nHostId  
);
```

Delete a virtual host associated with the specified server.

Parameters

nHostId

An integer value which identifies the virtual host.

Return Value

If the method succeeds, the return value is non-zero. If the server handle is invalid or the virtual host ID does not specify a valid host, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **DeleteVirtualHost** method removes a virtual host that was created by a previous call to the **AddVirtualHost** method. All virtual paths and users associated with the specified host are no longer valid. It is not necessary to call this method to delete any of the virtual hosts prior to stopping the server. Part of the normal shutdown process is releasing the resources allocated for each virtual host that was added to the server.

This method cannot be used to delete the virtual host with an ID of zero, which is the default virtual host that is allocated when the server is started.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

CHttpServer::DeleteVirtualPath Method

```
BOOL DeleteVirtualPath(  
    UINT nHostId,  
    LPCTSTR lpszVirtualPath  
);
```

Remove a virtual path from the specified host.

Parameters

nHostId

An integer value which identifies the virtual host.

lpszVirtualPath

A pointer to a string which specifies the virtual path that will be removed. This path must be absolute and cannot be a NULL pointer or an empty string.

Return Value

If the method succeeds, the return value is non-zero. If the virtual host ID does not specify a valid host, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

This method removes a virtual path that was created by a previous call to the **AddVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::DeleteVirtualUser Method

```
BOOL DeleteVirtualUser(  
    UINT nHostId,  
    LPCTSTR lpszUserName  
);
```

Remove a virtual user from the specified host.

Parameters

nHostId

An integer value which identifies the virtual host.

lpszUserName

A pointer to a string which specifies the user that will be removed. This parameter cannot be a NULL pointer or an empty string.

Return Value

If the method succeeds, the return value is non-zero. If the the virtual host ID does not specify a valid host, or the username does not exist, the method will return zero. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

This method removes a virtual user that was created by a previous call to the **AddVirtualUser** method. This method will not match partial usernames and wildcard characters cannot be used to delete multiple users. Usernames are not case sensitive.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::DetachHandle Method

```
HSERVER DetachHandle();
```

The **DetachHandle** method detaches the server handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the server handle associated with the current instance of the class object. If there is no active server, the value INVALID_SERVER will be returned.

Remarks

This method is used to detach a server handle created by the class for use with the SocketTools API. Once the server handle is detached from the class, no other class member functions may be called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[AttachHandle](#), [GetHandle](#)

CHttpServer::DisableCommand Method

```
BOOL EnableCommand(  
    LPCTSTR lpszCommand  
);
```

Disable a specific server command.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command to be disabled. The command name is not case-sensitive, but the value must otherwise match the exact name. Partial matches are not recognized by this method. This parameter cannot be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the command is not recognized, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **DisableCommand** method is used to disable access to a specific command on the server, typically for security purposes. For example, the PUT command can be disabled, preventing any client from attempting to upload files directly to the server. The **IsCommandEnabled** method can be used to determine if a command is enabled or not.

The command name provided to this method must match the commands defined in RFC 2616 or related protocol standards. Refer to [Hypertext Transfer Protocol Commands](#) for a complete list of server commands.

Some commands cannot be disabled because they are required to perform essential server functions. For example, the GET and HEAD commands cannot be disabled. If you attempt to disable a required command, this method will return zero and the last error code will be set to ST_ERROR_COMMAND_REQUIRED. Because this method affects all clients connected to the server, it should not be used to limit access to certain commands for specific clients. Instead, use an event handler to filter the commands.

The OPTIONS and TRACE commands are disabled by default for all server instances and must be explicitly enabled using the **EnableCommand** method if you wish permit clients to use them. It is not recommended that you enable these commands if your server is going to be publicly accessible over the Internet. If the server started with the option HTTP_SERVER_READONLY, commands that can be used to create or modify files on the server will be disabled by default.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::DisableTrace Method

BOOL DisableTrace();

Disable the logging of network function calls.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[EnableTrace](#)

CHttpServer::DisconnectClient Method

```
BOOL DisconnectClient(  
    UINT nClientId  
);
```

Close the control connection for the specified client and release the resources allocated for the session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **DisconnectClient** method will close the control channel, disconnecting the client from the server and terminating the client session thread. Resources that we allocated for the client, such as memory and open handles, will be released back to the operating system. If the client was in the process of transferring a file, the transfer will be aborted. This performs the same operation as if the client sent the QUIT command to the server.

This method sends an internal control message that notifies the server that this session should be terminated. When the session thread is signaled that it should terminate, it will abort any active file transfers and begin to release the resources allocated for that session. To ensure that the client session terminates gracefully, there may be a brief period of time where the session thread is still active after this method has returned.

After this method returns, the application should never use the same client ID with another method. Client IDs are unique to the session over the lifetime of the server, and are not reused.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

CHttpServer::EnableClientAccess Method

```
BOOL EnableClientAccess(  
    UINT nClientId,  
    DWORD dwUserAccess,  
    BOOL bEnable  
);
```

Enable or disable access rights for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies an access right to enable or disable. For a list of user access rights that can be granted to the client, see [User and File Access Constants](#).

bEnable

An integer value which specifies if permission should be granted or revoked for the specified access right. If this value is non-zero, permission is granted to the client to perform the action specified by the *dwUserAccess* parameter. If this value is zero, that permission is revoked.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **EnableClientAccess** method is used to enable or disable access to specific functionality by the client. The method can only change a single access right and cannot be used to enable or disable multiple access rights in a single method call. To change multiple user access rights for the client, use the **SetClientAccess** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

CHttpServer::EnableCommand Method

```
BOOL EnableCommand(  
    LPCTSTR lpszCommand  
);
```

Enable a specific server command.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command to be enabled or disabled. The command name is not case-sensitive, but the value must otherwise match the exact name. Partial matches are not recognized by this method. This parameter cannot be NULL.

bEnable

An integer value which specifies if the command should be enabled or disabled. If the value is non-zero, the command is enabled. If the value is zero, the command will be disabled.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **EnableCommand** method is used to enable access to a specific command on the server. The **IsCommandEnabled** method can be used to determine if a command is enabled or not. The command name provided to this method must match the commands defined in RFC 2616 or related protocol standards. Refer to [Hypertext Transfer Protocol Commands](#) for a complete list of server commands.

The OPTIONS and TRACE commands are disabled by default for all server instances and must be explicitly enabled using the **EnableCommand** method if you wish permit clients to use them. It is not recommended that you enable these commands if your server is going to be publicly accessible over the Internet. If the server started with the option HTTP_SERVER_READONLY, commands that can be used to create or modify files on the server will be disabled by default.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AuthenticateClient](#), [DisableCommand](#), [IsCommandEnabled](#)

CHttpServer::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

Enable the logging of network function calls to a file.

Parameters

lpszTraceFile

A pointer to a string that specifies the name of the log file. If this parameter is NULL or points to an empty string, a log file is created in the temporary directory for the current user.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_DEFAULT	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail, or return values which indicate a warning, are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call [GetLastError](#).

Remarks

When trace logging is enabled, the log file is opened, appended to and closed for each socket function call. Using the same file name, you can do the same in your application to add additional information to the file if needed. This can provide an application-level context for the entries made by the library. Make sure that the file is closed after the data has been written. If a file name is not specified by the caller, a file named **cstrace.log** will be created in the temporary directory for the current user.

The TRACE_HEXDUMP option can produce very large files, since all data that is being sent and received by the application is logged. To reduce the size of the file, you can enable and disable logging around limited sections of code that you wish to analyze.

To redistribute an application that includes this debug logging functionality, the **cstrcv11.dll** library must be included as part of the installation package. This library provides the trace logging features, and if it is not available the **EnableTrace** method will fail. Note that this is a standard Windows DLL and does not need to be registered, it only needs to be redistributed with your application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DisableTrace](#)

CHttpServer::EnumClients Method

```
INT EnumClients(  
    UINT *lpClients,  
    INT nMaxClients  
);
```

Return a list of active client connections established with the server.

Parameters

lpClients

Pointer to an array of unsigned integers which will contain client IDs that uniquely identifies each client when the method returns. If this parameter is NULL, then the method will return the number of active client connections established with the server.

nMaxClients

Maximum number of client IDs to be returned in the *lpClients* array. If the *lpClients* parameter is NULL, this parameter should have a value of zero.

Return Value

If the method succeeds, the return value is the number of active client connections to the server. If the method fails, the return value is HTTP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the *nMaxClients* parameter is less than the number of active client connections, the method will fail and the last error code will be set to the error ST_ERROR_BUFFER_TOO_SMALL. To dynamically determine the number of active connections, call the method with the *lpClients* parameter with a value of NULL, and the *nMaxClients* parameter with a value of zero.

Example

```
// Populate a listbox with all of the users connected to the server  
pListBox->ResetContent();  
  
INT nClients = pHttpServer->EnumClients();  
if (nClients > 0)  
{  
    UINT *pIdList = new UINT[nClients];  
  
    nClients = pHttpServer->EnumClients(pIdList, nClients);  
    if (nClients == HTTP_ERROR)  
    {  
        // Unable to obtain list of connected clients  
        return;  
    }  
  
    for (INT nIndex = 0; nIndex < nClients; nIndex++)  
    {  
        CString strUserName;  
  
        if (pHttpServer->GetClientUserName(pIdList[nIndex], strUserName))  
            pListBox->AddString(strUserName);  
    }  
  
    // Free the memory allocated for the client IDs  
    delete pIdList;
```

```
}
```

Requirements

[GetClientAddress](#), [GetClientDirectory](#), [GetClientUserName](#)

CHttpServer::GetActiveClient Method

```
UINT GetActiveClient();
```

Return the client ID for the active client session associated with the current thread.

Parameters

None.

Return Value

If the method succeeds, the return value is the unique ID associated with the client session for the current thread. If there is no client session active on the current thread, the return value is zero.

Remarks

The **GetActiveClient** method is used to obtain the client ID associated with the current thread. This means this method will only return a client ID if it is called within an event handler or a method called by an event handler. If this method is called by a function that is not executing within the context of an event handler it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

[EnumClients](#)

CHttpServer::GetAddress Method

```
INT GetAddress(  
    UINT nClientId,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetAddress(  
    UINT nClientId,  
    CString& strAddress  
);
```

Return the IP address of the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszAddress

A pointer to a string buffer that will contain the server IP address, terminated with a null character. To accommodate both IPv4 and IPv6 addresses, this buffer should be at least 46 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If either the client ID is invalid, or the buffer is not large enough to store the complete address, the method will return a value of zero.

Remarks

This method will return the IP address assigned to the specified server as a printable string. If the *nClientId* parameter has a value of zero, this method will return the IP address assigned to the local system. If the HTTP_SERVER_NATROUTER option was specified when the server was started, this method will return the external IP address assigned to the system. If the *nClientId* parameter specifies a valid client session, this method will return the IP address that the client used to establish the connection with the server. To determine the IP address assigned to the client, use the **GetClientAddress** method.

The format and length of IPv4 and IPv6 address strings are very different. An IPv4 address string looks like "192.168.0.20", while an IPv6 address string can look something like "fd7c:2f6a:4f4f:ba34::a32". If your application checks for the format of these address strings, it needs to be aware of the differences. You also need to make sure that you're providing enough space to display or store an address to avoid buffer overruns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientAddress](#), [GetName](#)

CHttpServer::GetClientAccess Method

```
BOOL GetClientAccess(  
    UINT nClientId,  
    DWORD& dwUserAccess  
);
```

Return the access rights that have been granted to the client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more access rights for the client session. For a list of user access rights that can be granted to the client, see [User and File Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method can only be used with authenticated clients. If the client session has not been authenticated, the return value will be zero.

Remarks

The **GetClientAccess** method is used to obtain all of the access rights that are currently granted to an authenticated client session. The **EnableClientAccess** method can be used to enable or disable specific permissions, and the **SetClientAccess** method can change multiple access rights at once.

Example

```
DWORD dwUserAccess = 0;  
  
// Check if the client has execute permission  
if (pHttpServer->GetClientAccess(nClientId, dwUserAccess))  
{  
    if (dwUserAccess & HTTP_ACCESS_EXECUTE)  
    {  
        std::cout << "Client can execute programs and scripts\n";  
        return;  
    }  
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[AuthenticateClient](#), [EnableClientAccess](#), [SetClientAccess](#)

CHttpServer::GetClientAddress Method

```
INT GetClientAddress(  
    UINT nClientId,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT GetClientAddress(  
    UINT nClientId,  
    CString& strAddress  
);
```

Return the IP address of the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszAddress

A pointer to a string buffer that will contain the client IP address, terminated with a null character. To accommodate both IPv4 and IPv6 addresses, this buffer should be at least 46 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID is invalid, or the buffer is not large enough to store the complete address, the method will return a value of zero.

Remarks

The format and length of IPv4 and IPv6 address strings are very different. An IPv4 address string looks like "192.168.0.20", while an IPv6 address string can look something like "fd7c:2f6a:4f4f:ba34::a32". If your application checks for the format of these address strings, it needs to be aware of the differences. You also need to make sure that you're providing enough space to display or store an address to avoid buffer overruns.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetAddress](#)

CHttpServer::GetClientCredentials Method

```
BOOL GetClientCredentials(  
    UINT nClientId,  
    LPHTTPCLIENTCREDENTIALS lpCredentials  
);
```

```
BOOL GetClientCredentials(  
    UINT nClientId,  
    CString& strUserName,  
    CString& strPassword  
);
```

Return the user credentials for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpCredentials

A pointer to an **HTTPCLIENTCREDENTIALS** structure that will contain information about the user when the method returns. This parameter cannot be NULL.

strUserName

A string that will contain the user name when the method returns. This version of the method is only available for MFC and ATL based projects that define the **CString** object.

strPassword

A string that will contain the user password when the method returns. This version of the method is only available for MFC and ATL based projects that define the **CString** object.

Return Value

If the user credentials for the client session are available, the return value is non-zero. If the client ID does not specify a valid client session, or the client has not requested authentication, this method will return zero.

Remarks

The **GetClientCredentials** method is used to obtain the username and password that was provided by the client when it requested authentication. Typically this method is used in an event handler to validate the credentials provided by the client. If the credentials are considered valid, the event handler would then call the **AuthenticateClient** method to specify that the session has been authenticated.

If the default event handler is used, the **OnAuthenticate** method will be invoked with the user credentials passed to the handler as arguments.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetClientDirectory Method

```
INT GetClientDirectory(  
    UINT nClientId,  
    LPTSTR lpszDirectory,  
    INT nMaxLength  
);
```

```
INT GetClientDirectory(  
    UINT nClientId,  
    CString& strDirectory  
);
```

Returns the root document directory for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszDirectory

A pointer to a string buffer that will contain the root document directory for the specified client session, terminated with a null character. This buffer should be at least MAX_PATH characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be larger than zero or the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero.

Remarks

This method returns the full path to the root document directory for the specified client session. If no virtual hosts have been configured, then this value will be the same as the root directory assigned to the server when it was started. If the server has been configured with multiple virtual hosts, this function will return the path to the root directory associated with the hostname provided by the client.

To convert a full path to the virtual path for a specific client session, use the **GetClientVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetClientVirtualPath](#)

CHttpServer::GetClientHeader Method

```
INT GetClientHeader(  
    UINT nClientId,  
    UINT nHeaderType,  
    LPCTSTR lpszHeaderName,  
    LPTSTR lpszHeaderValue,  
    INT nMaxLength,  
);
```

Return the value of a request or response header for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nHeaderType

Specifies the type of header. It may be one of the following values:

Value	Description
HTTP_HEADERS_REQUEST	Return the value of a request header that was provided by the client. Request header values provide additional information to the server about the type of request being made.
HTTP_HEADERS_RESPONSE	Return the value of a response header that was created by the server. Response header values provide additional information to the client about the type of information that is being returned by the server.

lpszHeaderName

A pointer to a string that specifies the name of the header field. Header names are not case-sensitive and should not include the colon which acts as a delimiter that separates the header name from its value. This parameter cannot be a NULL pointer or an empty string.

lpszHeaderValue

A pointer to a buffer that will contain the header value, terminated with a null character. To determine the length of the header value, this parameter can be NULL and the *nMaxLength* parameter should be specified with a value of zero.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the header value buffer, including the terminating null character. If the *lpszHeaderValue* parameter is NULL, this value must be zero.

Return Value

If the method succeeds, the return value is the length of the header value, not including the terminating null character. If the client ID does not specify a valid client session, or there is no header that matches the given name, the method will return zero. If the *lpszHeaderValue* parameter is not NULL and the buffer is not large enough to store the complete header value, the method will return zero and the last error code will be set to ST_ERROR_BUFFER_TOO_SMALL. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **GetClientHeader** method will return the value of a request or response header for the specified client session. If the *lpSzHeaderName* value matches an existing header field, its value will be copied to the string buffer provided by the caller.

Refer to [Hypertext Transfer Protocol Headers](#) for a list of common request and response headers that are used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetClientIdleTime Method

```
UINT GetClientIdleTime(  
    UINT nClientId,  
    UINT *lpnElapsed  
);
```

Return the idle timeout period for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpnElapsed

An optional pointer to an unsigned integer value that will contain the number of seconds the client session has been idle. This parameter may be NULL or omitted if this information is not required.

Return Value

If the method succeeds, the return value is client idle timeout period in seconds. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **GetClientIdleTime** method will return the number of seconds that the client may remain idle before being automatically disconnected by the server. The idle time of a client session is based on the last time a command was issued to the server or when a data transfer completed. The server will never disconnect a client that is in the process of sending or receiving data, regardless of the idle timeout period.

The default idle timeout period for a client session is 60 seconds, however the server can be configured to use a different value. The minimum timeout period for a client is 10 seconds, the maximum is 300 seconds (5 minutes). An application can change the timeout period for a specific client session using the **SetClientIdleTime** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[SetClientIdleTime](#)

CHttpServer::GetClientLocalPath Method

```
INT GetClientLocalPath(  
    UINT nClientId,  
    LPCTSTR lpszVirtualPath,  
    LPTSTR lpszLocalPath,  
    INT nMaxLength,  
);
```

```
INT GetClientLocalPath(  
    UINT nClientId,  
    LPCTSTR lpszVirtualPath,  
    CString& strLocalPath  
);
```

Return the full local path for a virtual filename or directory on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszVirtualPath

A pointer to a string that specifies an virtual path on the server. This parameter cannot be NULL.

lpszLocalPath

A pointer to a string buffer that will contain the full local path, terminated with a null-character. This buffer should be at least MAX_PATH characters to accommodate the complete path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the string buffer is not large enough to contain the complete path, this method will return zero and the last error code will be set to ST_ERROR_BUFFER_TOO_SMALL.

Remarks

The **GetClientLocalPath** method takes a virtual path and returns the full path to the specified file or directory on the local system. The virtual path may be absolute or relative to the root directory for the client session.

To obtain the virtual path for a local file or directory, use the **GetClientVirtualPath** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientVirtualPath](#)

CHttpServer::GetClientServer Method

```
HSERVER HttpGetClientServer(  
    UINT nClientId  
);
```

The **GetClientServer** method returns a handle to the server that created the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is the handle to the server that created the client session. If the method fails, the return value is INVALID_SERVER. To get extended error information, call the **GetLastError** method.

Remarks

The **GetClientServer** method returns the handle to the server that created the client session and is typically used within a notification message handler. If the server is in the process of shutting down, or the client session thread is terminating, this method will fail and return INVALID_SERVER indicating that the session ID is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h.

Import Library: cshtsv11.lib

See Also

[AsyncNotify](#)

CHttpServer::GetClientThreadId Method

```
DWORD GetClientThreadId(  
    UINT nClientId  
);
```

Returns the thread ID associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the method succeeds, the return value is a thread ID. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **GetClientThreadId** method returns a thread ID that can be used to identify the thread that is managing the client session. The thread ID can be used with other Windows API functions such as **OpenThread**. Exercise caution when using thread-related functions, interfering with the normal operation of the thread can have unexpected results. You should never use this method to obtain a thread handle and then call the **TerminateThread** function to terminate a client session. This will prevent the thread from releasing the resources that were allocated for the session and can leave the server in an unstable state. To terminate a client session, use the **DisconnectClient** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[EnumClients](#), [GetActiveClient](#)

CHttpRequest::GetClientUserName Method

```
INT GetClientUserName(  
    UINT nClientId,  
    LPTSTR lpszUserName,  
    INT nMaxLength  
);
```

```
INT GetClientUserName(  
    UINT nClientId,  
    CString& strUserName  
);
```

Return the user name associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

strUserName

A pointer to a string buffer that will contain the user name associated with the client session. This buffer must be large enough to store the complete user name, including the terminating null character. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, or the client has not authenticated itself, the method will return zero and the *lpszUserName* parameter will be set to an empty string.

The **IsClientAuthenticated** method can be used to determine if the client has provided credentials as part of the request made to the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[AuthenticateClient](#), [GetClientAccess](#)

CHttpServer::GetClientVariable Method

```
INT GetClientVariable(  
    UINT nClientId,  
    LPCTSTR lpszName,  
    LPTSTR lpszValue,  
    INT nMaxLength,  
);  
  
INT GetClientVariable(  
    UINT nClientId,  
    LPCTSTR lpszName,  
    CString& strValue  
);
```

Return the value of a CGI environment variable for the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszName

A pointer to a string that specifies the name of the environment variable. Variable names are not case-sensitive and should not include the equal sign which acts as a delimiter that separates the variable name from its value. This parameter cannot be a NULL pointer or an empty string.

lpszValue

A pointer to a buffer that will contain the value of the environment variable, terminated with a null character. To determine the length of the header value, this parameter can be NULL and the *nMaxLength* parameter should be specified with a value of zero.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the value buffer, including the terminating null character. If the *lpszValue* parameter is NULL, this value must be zero.

Return Value

If the method succeeds, the return value is the length of the environment variable value, not including the terminating null character. If the client ID does not specify a valid client session, or there is no environment variable that matches the given name, the method will return zero. If the *lpszValue* parameter is not NULL and the buffer is not large enough to store the complete header value, the method will return zero and the last error code will be set to `ST_ERROR_BUFFER_TOO_SMALL`. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **GetClientVariable** method will return the value of an environment variable that has been defined for the client. Each client session inherits a copy of the process environment block, which is then modified to define various environment variables that are used with CGI programs and scripts. The **SetClientVariable** method can be used to change existing environment variables or create new variables.

The standard CGI environment variables that are defined by the server are not created until the client request has been processed. This means that environment variables such as `REMOTE_ADDR` and

SERVER_NAME will not be defined inside an **OnConnect** event handler.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[SetClientVariable](#)

CHttpServer::GetClientVirtualHost Method

```
INT GetClientVirtualHost(  
    UINT nClientId,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
INT GetClientVirtualHost(  
    UINT nClientId,  
    CString& strHostName  
);
```

Return the name of the virtual host the client used to establish the connection.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszHostName

A pointer to a string buffer that will contain the virtual host name. The string buffer will be null terminated and must be large enough to store the complete hostname. If this parameter is NULL, the method will only return the length of the current command in characters, not including the terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. If the maximum length specified is smaller than the actual length of the parameter, this method will fail. If the *lpszHostName* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **GetClientVirtualHost** method is used to obtain the hostname that the client used to establish a connection with the server. This method is typically used within an event handler to determine the hostname associated with the request made by the client. It should not be called inside an **OnConnect** event handler because the virtual host has not been selected at that point. If the virtual hostname is not available at the time this method is called, the method will return zero and the last error code will be set to ST_ERROR_VIRTUAL_HOST_NOT_FOUND.

The **GetClientVirtualHostId** method can be used to obtain the virtual host ID associated with the hostname.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetClientVirtualHostId](#), [GetCommandUrl](#), [GetVirtualHostName](#)

CHttpServer::GetClientVirtualHostId Method

```
UINT GetClientVirtualHostId(  
    UINT nClientId  
);
```

Return the virtual host ID associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

An unsigned integer value which specifies the virtual host ID. If the method fails, the return value will be INVALID_VIRTUAL_HOST and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **GetClientVirtualHostId** method is used to obtain the virtual host ID associated with the hostname the client used to establish a connection with the server. This method should not be called inside an **OnConnect** event handler because the virtual host has not been selected at that point. If the virtual host ID is not available at the time this method is called, the method will return INVALID_VIRTUAL_HOST and the last error code will be set to ST_ERROR_VIRTUAL_HOST_NOT_FOUND.

The **GetClientVirtualHost** method can be used to obtain the hostname that the client used to establish the connection.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

[GetClientVirtualHost](#), [GetCommandUrl](#), [GetVirtualHostId](#)

CHttpServer::GetClientVirtualPath Method

```
INT GetClientVirtualPath(  
    UINT nClientId,  
    LPCTSTR lpszLocalPath,  
    LPTSTR lpszVirtualPath,  
    INT nMaxLength,  
);
```

```
INT GetClientVirtualPath(  
    UINT nClientId,  
    LPCTSTR lpszLocalPath,  
    CString& strVirtualPath  
);
```

Return the virtual path for a local file on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszLocalPath

A pointer to a string that specifies an absolute path on the local system. This parameter cannot be NULL.

lpszVirtualPath

A pointer to a string buffer that will contain the virtual path, terminated with a null-character. This buffer should be at least MAX_PATH characters to accommodate the complete path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the string buffer is not large enough to contain the complete path, this method will return zero and the last error code will be set to ST_ERROR_BUFFER_TOO_SMALL.

Remarks

A virtual path for the client is relative to the root directory for the specified client session. These virtual paths are what the client will see as an absolute path on the server. For example, if the server was configured to use "C:\ProgramData\MyServer" as the root directory, and the *lpszLocalPath* parameter was specified as "C:\ProgramData\MyServer\Documents\Research", this method would return the virtual path to that directory as "/Documents/Research".

If the *lpszLocalPath* parameter specifies a file or directory outside of the server root directory, this method will return zero and the last error code will be set to ST_ERROR_INVALID_FILE_NAME. This method can only be used with authenticated clients. If the *nClientId* parameter specifies a client session that has not been authenticated, this method will return zero and the last error code will be ST_ERROR_AUTHENTICATION_REQUIRED.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#), [GetClientLocalPath](#)

CHttpServer::GetCommandFile Method

```
INT GetCommandFile(  
    UINT nClientId,  
    LPTSTR lpszFileName,  
    INT nMaxLength  
);
```

```
INT GetCommandFile(  
    UINT nClientId,  
    CString& strFileName  
);
```

Get the full path to a file name or directory specified by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string buffer that will contain the full path to a file name or directory specified by the client when it issued a command. The string buffer will be null terminated and must be large enough to store the complete file path. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. It is recommended that the buffer be at least MAX_PATH characters in size. If the maximum length specified is smaller than the actual length of the full path, this method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **GetCommandFile** method is used to obtain the full path to a local file name or directory specified by the client as an argument to a standard HTTP command. For example, if the client sends the GET command to the server, this method will return the complete path to the local file that the client wants to retrieve. This method will only work with those standard commands that perform some action on a file or directory.

This method should always be used to obtain the file name for a command that performs a file or directory operation. It normalizes the path provided by the client and ensures that it specifies a file or directory name in the correct location. The **GetCommandUrl** method can be used to obtain the URL that was provided by the client.

To map a virtual path to a file or directory on the local system, use the **AddVirtualPath** method. To redirect a client to use a different URL to access the resource, use the **RedirectRequest** method.

The **SetCommandFile** method can be used to change the name of the local file or directory that is the target of the command, however using this method to redirect access to a resource can have unintended side-effects, particularly in the case where the URL provided by the client actually resolves to an executable CGI program that handles the request.

If the client has provided a URL that resolves to a CGI program that handles the request, this method behaves differently than if the URL is resolved to a local file or directory. If the client uses the GET or POST command that results in a program being executed to handle the request, this method will return the path to the server root directory along with any additional path information provided in the URL. In other words, the file name returned by this method will be the same as the PATH_TRANSLATED value passed to the CGI program.

This method should only be called after the client request has been received by the server, typically inside a **OnCommand** or **OnExecute** event handler. It should not be called inside a **OnConnect** event handler because the server has not processed the client request at that point.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

    LPTSTR lpszCmdLine,  
    INT nMaxLength  
);  
  
INT GetCommandLine(  
    UINT nClientId,  
    CString& strCmdLine  
);
```

Return the complete command line issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCmdLine

A pointer to a string buffer that will contain the command, including all arguments. The string buffer will be null terminated and must be large enough to store the complete command line. If this parameter is NULL, the method will return the length of the command line. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. The internal limit on the maximum length of a command is 1024 characters. If the maximum length specified is smaller than the actual length of the complete command, this method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code has a value of zero then no command has been issued by the client.

Remarks

The **GetCommandLine** method is used to obtain the command that was issued by the client, and is commonly used inside the **OnCommand** and **OnResult** event handlers to pre-process and post-process client commands, respectively. When the method returns, the string buffer provided by the caller will contain the complete command, including the resource path and requested HTTP version. Any extraneous whitespace will be removed, however all encoding will be preserved.

To obtain the complete URL associated with the request issued by the client, use the **GetCommandUrl** method. If the command sent by the client is used to perform an action on a file or directory, the **GetCommandFile** method should be called to obtain the full path to the local file rather than using the resource path.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::GetCommandName Method

```
INT GetCommandName
    UINT nClientId,
    LPTSTR lpszCommand,
    INT nMaxLength
);

INT GetCommandName
    UINT nClientId,
    CString& strCommand
);
```

Return the name of the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string buffer that will contain the command name. The string buffer will be null terminated and must be large enough to store the complete parameter value. If this parameter is NULL, the method will only return the length of the current command in characters, not including the terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. If the maximum length specified is smaller than the actual length of the parameter, this method will fail. If the *lpszCommand* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the last error code is returned as a value of zero, this means that no command has been issued by the client.

Remarks

The **GetCommandName** method is used to obtain the name of the last command that was issued by the client. The command name returned by this method will always be capitalized, regardless of how it was sent by the client. This method is typically used inside the **OnCommand** and **OnResult** event handlers to pre-process and post-process client commands, respectively. It should not be called inside a **OnConnect** event handler because the server has not processed the client request at that point.

The **GetCommandUrl** function can be used to return the resource that was requested by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandFile](#), [GetCommandUrl](#), [OnCommand](#), [OnResult](#)

CHttpRequest::GetCommandQuery Method

```
INT GetCommandQuery(  
    UINT nClientId,  
    LPTSTR lpszParameters,  
    INT nMaxLength  
);  
  
INT GetCommandQuery(  
    UINT nClientId,  
    CString& strParameters  
);
```

Return the query parameters included with the command.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszParameters

A pointer to a string buffer that will contain the query parameters when the method returns. The string buffer will be null terminated up to the maximum number of characters specified by the caller. If this parameter is NULL the method will return the length of the query string. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. If the *lpszParameters* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code. If the client did not provide any query parameters, this method will return zero and the last error code will be zero.

Remarks

The **GetCommandQuery** method is used to obtain a copy of the query parameters that were included in the request URL. If there were no query parameters, the string buffer will be empty and the return value will be zero. If the request did include query parameters, they will be returned to the caller in their original, encoded form.

This method should not be called within an **OnConnect** event handler because the client request has not been processed at that point.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetCommandName](#), [GetCommandResource](#), [ReceiveRequest](#)

CHttpRequest::GetCommandResource Method

```
INT GetCommandResource(  
    UINT nClientId,  
    LPTSTR lpszResource,  
    INT nMaxLength  
);
```

```
INT GetCommandResource(  
    UINT nClientId,  
    CString& strUrlPath  
);
```

Return the URL path for the resource requested by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszResource

A pointer to a string buffer that will contain the URL path provided by the client for the current command. The string buffer will be null terminated and must be large enough to store the complete path. If this parameter is NULL, the method will only return the length of the path. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. If the *lpszResource* parameter is NULL, this value should be zero. If this value is less than the length of the URL, the method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **GetCommandResource** method returns the URL path that the client provided to access the requested resource. The path will not include the URI scheme, user credentials or query parameters. The **GetCommandFile** method can be used to determine the name of the local file on the server that will be accessed using this URL.

If you require the complete URL, not just the path to the resource, use the **GetCommandUrl** method.

This method should only be called after the client request has been received by the server, typically inside an **OnCommand** event handler. It should not be called inside a **OnConnect** event handler because the server has not processed the client request at that point.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetCommandResult Method

```
INT GetCommandResult(  
    UINT nClientId,  
    LPTSTR lpszResult,  
    INT nMaxLength  
);  
  
INT GetCommandResult(  
    UINT nClientId,  
    CString& strResult  
);
```

Return the result code and description for the last command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszResult

A pointer to a string buffer that will contain the description of the result code. The string buffer will be null terminated up to the maximum number of characters specified by the caller. This parameter can be NULL if this information is not required. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer. If the *lpszResult* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the result code for the last command issued by the client. A return value of zero indicates that the command has not completed and there is no result code available.

Remarks

The **GetCommandResult** method is used to determine the result of the last command that was issued by the client and is typically called in the **OnResult** event handler. This method should only be called after a command has been processed or the **SendResponse** method has been called.

The result code is a three-digit integer value that indicates the success or failure of a command. Whenever a client sends a command to the server, the server must respond with this numeric code and a brief description of the the result. Result codes are generally broken down into the following categories:

Result Code	Description
100-199	Result codes in this range are informational and only used with version 1.1 of the protocol. If the server returns a result code in this range, it means that it has received the request and that the client should proceed.
200-299	Result codes in this range indicate that the server has successfully completed the requested action. In most cases this means that the server has returned the requested data to the client, however if a 204 result code is sent, this indicates that the request has been processed but there is no data available.
300-399	Result codes in this range indicate that the requested resource has been moved to a

	new location. The most common result codes are 301 and 302. A value of 301 indicates that the location of the resource has changed permanently and all future requests should be sent to the new URL. A value of 302 indicates that the resource location has changed temporarily. The new location of the resource is sent to the client by setting the Location response header field.
400-499	Result codes in this range indicate an error with the request that was made by the client. These types of errors include invalid commands, requests that can only be issued by authenticated clients, or resources that cannot be accessed on the server. The most common result code in this range is the 404 code which indicates that the requested document could not be found.
500-599	Result codes in this range indicate a server error has occurred while processing a valid request. These types of errors are returned when a command has not been implemented, the execution of a CGI program or script has failed unexpectedly, or an internal server error has occurred.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[ReceiveRequest](#), [SendResponse](#), [OnResult](#)

CHttpRequest::GetCommandUrl Method

```
INT GetCommandUrl(  
    UINT nClientId,  
    LPTSTR lpzUrl,  
    INT nMaxLength  
);  
  
INT GetCommandUrl(  
    UINT nClientId,  
    CString& strUrl  
);
```

Return the complete URL of the resource requested by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpzUrl

A pointer to a string buffer that will contain the URL provided by the client for the current command. The string buffer will be null terminated and must be large enough to store the complete URL. If this parameter is NULL, the method will only return the length of the URL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. If the *lpzUrl* parameter is NULL, this value should be zero. If this value is less than the length of the URL, the method will fail.

Return Value

An integer value which specifies the number of characters copied into the buffer, not including the terminating null character. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **GetCommandUrl** method returns the complete URL that the client provided to access the requested resource. The URL will include any query parameters that were specified by the client, but it will not include any user credentials. The **GetCommandFile** method can be used to determine the name of the local file on the server that will be accessed using this URL.

If you only require the URL path, without the URI scheme or the query parameters, use the **GetCommandResource** method.

This method should only be called after the client request has been received by the server, typically inside an **OnCommand** event handler. It should not be called inside an **OnConnect** event handler because the server has not processed the client request at that point.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpRequest::GetDirectory Method

```
INT GetDirectory(  
    LPTSTR lpszDirectory,  
    INT nMaxLength  
);
```

```
INT GetDirectory(  
    CString& strDirectory  
);
```

Return the full path to the root directory assigned to the specified server.

Parameters

lpszDirectory

A pointer to a string buffer that will contain the server root directory, terminated with a null character. It is recommended that this buffer be at least MAX_PATH characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete path, the method will return a value of zero.

Remarks

The **GetDirectory** method will return the full path to the root directory assigned to the server instance. The root directory may be specified as part of the server configuration, or if no directory is specified by the application, the current working directory for the process will be used and this method can be used to obtain the full path to the directory. When the application specifies a root directory, it may use environment variables such as %AppData% in the path. This method will return the fully resolved path name, with all environment variables expanded.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpServer::GetHandle Method

```
HSERVER GetHandle();
```

The **GetHandle** method returns the server handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the server handle associated with the current instance of the class object. If the server is inactive, the value INVALID_SERVER will be returned.

Remarks

This method is used to obtain the server handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

[IsInitialized](#)

CHttpServer::GetIdentity Method

```
INT GetIdentity(  
    LPTSTR lpszIdentity,  
    INT nMaxLength  
);  
  
INT GetIdentity(  
    CString& strIdentity  
);
```

Return the identity of the specified server.

Parameters

lpszIdentity

A pointer to a string buffer that will contain the identity of the server when the method returns, terminated with a null character. This parameter cannot be NULL. It is recommended that this buffer be at least 32 characters in length. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete path, the method will return a value of zero.

Remarks

The **GetIdentity** method returns the identity string that was specified as part of the server configuration. It is used for informational purposes only and does not affect the operation of the server. Typically the string specifies the name of the application and a version number. The **SetIdentity** method can be used to change the identity string associated with the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetLastError Method

```
DWORD GetLastError(  
    LPTSTR lpszError,  
    INT nMaxLength  
);  
  
DWORD GetLastError(  
    CString& strError  
);  
  
DWORD GetLastError();
```

Return the last server error code and a description of the error.

Parameters

lpszError

A pointer to a string buffer that will contain a description of the error. If the error description is not needed, this parameter may be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the error string buffer, including the terminating null character. If the *lpszError* parameter is NULL, this value should be zero.

Return Value

An unsigned integer value that specifies the last error that occurred. A value of zero indicates that there was no error.

Remarks

Error codes are unsigned 32-bit values which are private to each server. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods clear the last error code when they succeed.

It is important to note that the error codes returned by this method are different than the command result codes that are defined in RFC 2616, the standard protocol specification for HTTP. This method is used to determine reason that an API function has failed, and should not be used to determine if a command issued by the client was successful. The **SendResponse** method is used to send responses to the client, and the **GetCommandResult** method can be used to determine the result of the last command sent by the client.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Failure is typically indicated by a return value such as FALSE, NULL, INVALID_SERVER or HTTP_ERROR. Those methods which clear the last error code when they succeed are noted on their reference page.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetCommandResult](#), [SendResponse](#), [SetLastError](#)

CHttpServer::GetLogFile Method

```
BOOL GetLogFile(
    UINT *lpnLogFormat,
    UINT *lpnLogLevel,
    LPTSTR lpszFileName,
    INT nMaxLength
);

BOOL GetLogFile(
    UINT *lpnLogFormat,
    UINT *lpnLogLevel,
    CString& strFileName
);

BOOL GetLogFile(
    CString& strFileName
);
```

Return the current log file format and the full path to the file.

Parameters

lpnLogFormat

A pointer to an integer value that will contain the log file format being used when the method returns. If this information is not needed, this parameter may be NULL. The following formats are supported:

Value	Description
HTTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
HTTP_LOGFILE_COMMON	This value specifies that the server should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about file transfers.
HTTP_LOGFILE_COMBINED	This value specifies that the server should use the combined log file format. This format is similar to the common format, however it includes the client referrer and user agent. This is the format that most Apache web servers use by default.
HTTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session.

lpnLogLevel

A pointer to an integer value that will contain the level of detail the server uses when generating the log file. The minimum value is 1 and the maximum value is 10. If this information is not needed, this parameter may be NULL.

lpszFileName

A pointer to a string buffer that will contain the full path to the log file. This parameter may be NULL if this information is not required. An alternate version of this method accepts a **CString** object if it

is available.

nMaxLength

An integer that specifies the maximum number of characters that can be copied into the file name string, including the terminating null character. If the *lpzFileName* parameter is NULL, this value should be zero.

Return Value

An integer value which specifies the current log file format. Refer to the **HTTPSERVERCONFIG** structure definition for a list of supported log file formats. If logging has not been enabled, this method will return a value of zero.

Remarks

If the server is configured with logging enabled, but a log file name is not explicitly provided, then the server will automatically generate one. This method can be used to get the full path to the current log file along with the format that is being used to record client session data. Normally the log file is held open by the server thread while it is active, however you can call the **RenameServerLogFile** method to explicitly rename or delete the log file.

To change the name of the log file, the log file format or level of detail, use the **SetLogFile** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[RenameServerLogFile](#), [SetLogFile](#)

GetMemoryUsage Method

```
SIZE_T GetMemoryUsage();
```

Return the amount of memory allocated for the server and all client sessions.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero and specifies the amount of memory allocated by the server. If the server is inactive or cannot be locked, the return value is zero. Call the **GetLastError** method to determine the cause of the failure.

Remarks

This method returns the amount of memory allocated by the server and all active client sessions. It enumerates all of memory allocations made by the server process and client session threads and returns the total number of bytes allocated for the server process. This value reflects the amount of memory explicitly allocated by this library and does not reflect the total working set size of the process, or memory allocated by any other libraries. To determine the working set size for the process, refer to the Win32 **GetProcessWorkingSetSize** and **GetProcessMemoryInfo** functions.

This method forces the server into a locked state, and all client sessions will block until the method returns. Because this method enumerates all heaps allocated for the server process, it can be an expensive operation, particularly when there are a large number of active clients connected to the server. Frequent use of this method can significantly degrade the performance of the server. It is primarily intended for use as a debugging tool to determine if memory usage is the result of an increase in active client sessions. If the value returned by the method remains reasonably constant, but the amount of memory allocated for the process continues to grow, it could indicate a memory leak in some other area of the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetName Method

```
INT GetName(  
    UINT nClientId,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
INT GetName(  
    UINT nClientId,  
    CString& strHostName  
);
```

Return the host name assigned to the specified server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszHostName

A pointer to a string buffer that will contain the server host name, terminated with a null character. It is recommended that this buffer be at least 64 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the client ID is invalid or the buffer is not large enough to store the complete hostname, the method will return a value of zero.

Remarks

This method will return the host name assigned to the specified server. If the *nClientId* parameter has a value of zero, the method will return the default host name that was specified as part of the server configuration. If no host name was explicitly assigned to the server, then it will return the local system name. If the *nClientId* parameter specifies a client session, then it this method will return the host name that the client used to establish the connection.

Requirements

[SetOptions](#)

CHttpServer::GetPriority Method

INT GetPriority();

Return the current priority assigned to the specified server.

Parameters

None.

Return Value

If the method succeeds, the return value is the priority for the specified server. If the method fails, the return value is HTTP_PRIORITY_INVALID. To get extended error information, call the **GetLastError** method.

Remarks

The **GetPriority** method can be used to determine the current priority assigned to the server. It will return one of the following values:

Value	Description
HTTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the server. It is typically used with lightweight services running in the background that are designed for few client connections. The server thread will be assigned a lower scheduling priority and will be frequently forced to yield execution to other threads.
HTTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the server and meters the processor utilization for the server thread. The server thread will be assigned a lower scheduling priority and will occasionally be forced to yield execution to other threads.
HTTP_PRIORITY_NORMAL	The default priority which balances resource and processor utilization. This is the priority that is initially assigned to the server when it is started, and it is recommended that most applications use this priority.
HTTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the server and the thread will be given higher scheduling priority. It is not recommended that this priority be used on a system with a single processor.
HTTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization. The server thread will be given higher scheduling priority and will be more responsive to client connection requests. It is not recommended that this priority be used on a system with a single processor.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpRequest::GetProgramExitCode Method

```
BOOL GetProgramExitCode(  
    UINT nClientId,  
    DWORD& dwExitCode  
);
```

Return the exit code of the last program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwExitCode

An unsigned integer that will contain the program exit code when the method returns.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **GetProgramExitCode** method returns the exit code of a registered CGI program or script that was executed. By convention, most programs return an exit code in the range of 0-255, with an exit code of zero indicating success. The exit code is commonly used by programs to communicate status information back to the server application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

CHttpServer::GetProgramName Method

```
INT GetProgramName(  
    UINT nClientId,  
    LPTSTR lpszProgramName,  
    INT nMaxLength  
);  
  
INT GetProgramName(  
    UINT nClientId,  
    CString& strProgramName  
);
```

Return the name of the CGI program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszProgramName

A pointer to a string buffer that will contain the name of the CGI program executed by the client. This parameter cannot be NULL and should be at least MAX_PATH characters in size. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters that can be copied into the string buffer, including the terminating null character. This parameter must have a value greater than zero.

Return Value

If the method succeeds, the return value is the length of the executable file name. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed a CGI program this method will return zero and the last error code will be set to zero.

Remarks

The **GetProgramName** method returns the local file name of the CGI program that was executed in response to a request from the client. This is the full path to the executable that was registered with the server using the **RegisterProgram** method. If the client specified a regular document or directory, this method will return a value of zero, indicating that no CGI program has been executed to handle the request.

To obtain the resource URL that was provided by the client, use the **GetCommandUrl** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetProgramExitCode](#), [GetProgramOutput](#), [RegisterProgram](#)

CHttpRequest::GetProgramOutput Method

```
DWORD GetProgramOutput(  
    UINT nClientId,  
    LPBYTE lpBuffer,  
    DWORD dwBufferSize  
);
```

Return a copy of the standard output from the a CGI program executed by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpBuffer

A pointer to a buffer that will contain the output from the last program executed by the client. If this parameter is NULL, the method will return the number of bytes of data that was output by the program. Note that this output is not null terminated.

dwBufferSize

The maximum number of bytes that can be copied into the buffer. If the *lpBuffer* parameter is NULL, this value should be zero.

Return Value

If the method succeeds, the return value is the number of bytes copied into the specified buffer. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed any programs, the return value will be zero.

Remarks

The **GetProgramOutput** method is used to obtain a copy of the output generated by a CGI program. To determine the number of bytes of output available to read, call this method with the *lpBuffer* parameter as NULL and the *dwBufferSize* parameter with a value of zero. The return value will be the number of bytes of data that was output by the program. It should be noted that for Unicode builds, the buffer is a byte array, not an array of characters, and will not be null terminated.

This method returns the raw output from the program which may contain a response header block, escape sequences, control characters and embedded nulls. When the application processes the output returned by this method, it should never coerce the buffer pointer to an LPTSTR value because there is no guarantee that the data will be null-terminated. To obtain the output from the program as a null-terminated string, use the **GetProgramText** method.

This method should only be used within an **OnExecute** event handler, which occurs after the program has terminated.

Example

```
LPBYTE lpBuffer = NULL; // A pointer to the output buffer  
DWORD cbBuffer = 0;     // Number of bytes in the output buffer  
  
// Determine the number of bytes in the output buffer  
cbBuffer = pHttpRequest->GetProgramOutput(nClientId, NULL, 0);  
  
if (cbBuffer > 0)  
{  
    // Allocate memory for the buffer
```

```
lpBuffer = new BYTE[cbBuffer + 1];

// Copy the program output to the buffer
cbBuffer = pHttpServer->GetProgramOutput(nClientId, lpBuffer, cbBuffer + 1);
}

// Free the memory allocated for the buffer when finished
if (lpBuffer != NULL)
{
    delete lpBuffer;
    lpBuffer = NULL;
    cbBuffer = 0;
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[GetProgramExitCode](#), [GetProgramText](#), [OnExecute](#), [RegisterProgram](#)

CHttpRequest::GetProgramText Method

```
INT GetProgramText(  
    UINT nClientId,  
    LPTSTR lpszBuffer,  
    INT nMaxLength  
);  
  
INT GetProgramText(  
    UINT nClientId,  
    CString& strBuffer  
);
```

Return a copy of the standard output from a CGI program in a string buffer.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszBuffer

A pointer to a buffer that will contain the output from the last program executed by the client as a string. If this parameter is NULL, the method will return the number of bytes of characters that was output by the program, not including a terminating null character. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

The maximum number of bytes that can be copied into the buffer. If the *lpszBuffer* parameter is NULL, this value should be zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the specified string buffer, not including the terminating null character. If the client ID does not specify a valid client session, the method will return zero. If the client has not executed any programs, the return value will be zero.

Remarks

The **GetProgramText** method is used to obtain a copy of the output generated by a CGI program. To determine the number of characters of output available to read, call this method with the *lpszBuffer* parameter as NULL and the *nMaxLength* parameter with a value of zero. The return value will be the number of characters that were output by the program. If the application dynamically allocates the string buffer, make sure that it allocates an extra character for the terminating null character.

This method will only return textual output from the program and any non-printable control characters and the escape character will be replaced with a space. To obtain the unfiltered output from the program, use the **GetProgramOutput** method. If the program outputs a response header block, this will be included in the string buffer.

This method should only be used within an **OnExecute** event handler, which occurs after the program has terminated.

Example

```
CString strBuffer;
```

```
if (pHttpServer->GetProgramText(nClientId, strBuffer) > 0)
    pEditCtrl->SetWindowText(strBuffer);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetProgramExitCode](#), [GetProgramOutput](#), [OnExecute](#), [RegisterProgram](#)

CHttpServer::GetStackSize Method

DWORD GetStackSize();

Return the initial size of the stack allocated for threads created by the server.

Parameters

None.

Return Value

If the method succeeds, the return value is the amount of memory that will be allocated for the stack in bytes. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **GetStackSize** method returns the initial amount of memory that is committed to the stack for each thread created by the server. By default, the stack size for each thread is set to 256K for 32-bit processes and 512K for 64-bit processes.

If this method is called when the server is not active, it will return the default stack size that the server will be configured to use when it starts. In this case, a return value of zero specifies that the default stack size will be used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h.

Import Library: cshtsv11.lib

See Also

CHttpServer::GetTransferInfo Method

```
BOOL GetTransferInfo(  
    UINT nClientId,  
    LPHTTPSERVERTRANSFER lpTransferInfo  
);
```

Return information about the current file transfer.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpTransferInfo

A pointer to an **HTTPSERVERTRANSFER** structure that will contain information about the last file transfer. This parameter cannot be NULL, and the *dwSize* member of the structure must be initialized to specify the structure size prior to calling this method.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method should only be called after the client has issued the GET or PUT commands to initiate a file transfer, otherwise the return value will be zero.

Remarks

The **GetTransferInfo** method is used to obtain information about the last file transfer that was performed by the client. This method is typically called within an event handler to determine how many bytes of data were transferred, the type of file and the full path to the file on the local system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::GetUuid Method

```
INT GetUuid(  
    LPTSTR lpszHostUuid,  
    INT nMaxLength  
);  
  
INT GetUuidString(  
    CString& strHostUuid  
);
```

Return the UUID assigned to the server as a printable string.

Parameters

lpszHostUuid

A pointer to a string buffer that will contain the server UUID, terminated with a null character. It is recommended that this buffer be at least 40 characters in length. This parameter cannot be NULL. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. This value must be greater than zero. If the buffer size is too small, the method will fail.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If the buffer is not large enough to store the complete UUID string, the method will return a value of zero.

Remarks

The **GetUuid** method returns the Universally Unique Identifier (UUID) that has been assigned to the server. The UUID may either be generated by the application and assigned as part of the server configuration, or an ephemeral UUID may be automatically generated when the server is started.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[SetUuid](#)

CHttpServer::GetVirtualHostId Method

```
UINT GetVirtualHostId(  
    LPCTSTR lpszHostName,  
    UINT nHostPort  
);
```

Return the virtual host ID associated with the specified hostname.

Parameters

lpszHostName

A string that specifies the virtual host name.

nHostPort

An optional integer value which specifies the port number for the virtual host. If this parameter is specified it must be the same value as the original port number that the server was configured to use.

Return Value

If the method succeeds, the return value is the host ID that uniquely identifies the virtual host. If the server handle is invalid, or there is no virtual host with the specified name, the method will return VIRTUAL_HOST_UNKNOWN. If the method fails, the last error code will be updated to indicate the cause of the failure.

Remarks

The **GetVirtualHostId** method is used to obtain the unique virtual host ID that is associated with a specific hostname. This method will match both the primary virtual hostname added using the **AddVirtualHost** method, as well as any aliases that were added using the **AddVirtualHostAlias** method. To obtain the virtual host ID associated with the active client session, use the **GetClientVirtualHostId** method.

The *nHostPort* parameter should either be omitted or specified with the same port number that the server was configured to use. Port-based virtual hosting is currently not supported and this parameter is included for future use.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[AddVirtualHost](#), [AddVirtualHostAlias](#), [DeleteVirtualHost](#), [GetClientVirtualHostId](#), [GetVirtualHostName](#)

CHttpServer::GetVirtualHostName Method

```
INT GetVirtualHostName(  
    UINT nHostId,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);  
  
INT GetVirtualHostName(  
    UINT nHostId,  
    CString& strHostName  
);
```

Return the hostname associated with the specified virtual host ID.

Parameters

hServer

The server handle.

nHostId

An integer value which identifies the virtual host.

lpszHostName

A pointer to a string buffer that will contain the virtual host name, terminated with a null character. It is recommended that this buffer be at least 64 characters in length. If this parameter is NULL, the method will return the length of the virtual hostname. An alternate version of this method accepts a **CString** object if it is available.

nMaxLength

An integer value that specifies the maximum number of characters can be copied into the string buffer, including the terminating null character. If the *lpszHostName* parameter is NULL this value must be zero.

Return Value

If the method succeeds, the return value is the number of characters copied into the string buffer, not including the terminating null character. If either the server handle or the host ID is invalid, or the buffer is not large enough to store the complete hostname, the method will return a value of zero.

Remarks

The **GetVirtualHostName** method returns the primary hostname associated with the specified virtual host ID. This is the same hostname that was specified when the virtual host was added to the server configuration using the **AddVirtualHost** method. To obtain the hostname that was used by the active client session to connect to the server, use the **GetClientVirtualHost** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::IsActive Method

BOOL IsActive();

Determine if the server has been started.

Return Value

This method returns a non-zero value if the server has been started. If the server is stopped this method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[CHttpServer](#), [IsListening](#), [Start](#), [Stop](#)

CHttpServer::IsClientAuthenticated Method

```
BOOL IsClientAuthenticated(  
    UINT nClientId  
);
```

Determine if the specified client session has been authenticated.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

If the client session has been authenticated, this method will return a non-zero value, otherwise it will return zero. If the client ID is valid, this method will clear the last error code.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[AuthenticateClient](#), [GetClientCredentials](#), [RequireAuthentication](#)

CHttpServer::IsCommandEnabled Method

```
BOOL IsCommandEnabled(  
    LPCTSTR lpszCommand  
);
```

Determine if a specific server command has been enabled or disabled.

Parameters

lpszCommand

A pointer to a NULL terminated string that specifies the name of the command. The command name is not case-sensitive, but the value must otherwise match the exact command name. Partial matches are not recognized by this method. This parameter cannot be NULL.

Return Value

If the command is enabled, this method will return a non-zero value. If the command is disabled or the command name does not match a supported command, this method will return zero.

Remarks

The **IsCommandEnabled** method is used to determine whether a specific command is enabled. Typically this method is used in an event handler to make sure the command issued by a client is recognized by the server and enabled for use. Commands can be enabled using the **EnableCommand** method and disabled using the **DisableCommand** method.

This method does not account for the permissions granted to a specific client session. Clients are assigned access rights when they are authenticated using the **AuthenticateClient** method, and certain commands can be limited by the permissions granted to the client. For example, even if the PUT command is enabled, a client must have the HTTP_ACCESS_WRITE permission to use the command to upload a file to the server. For a list of access rights, see [User Access Constants](#).

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[CHttpServer](#)

CHttpServer::IsListening Method

BOOL IsListening();

Determine if the server is listening for client connections.

Return Value

This method returns a non-zero value if the server has been started and is listening for client connections. If the server is stopped or has been suspended this method will return zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[CHttpServer](#), [IsActive](#), [Start](#), [Stop](#)

CHttpServer::PreProcessEvent Method

```
virtual LONG PreProcessEvent(  
    HSERVER hServer,  
    UINT nClientId,  
    UINT nEventId,  
    DWORD dwError,  
    BOOL& bHandled  
);
```

A virtual method that is invoked for each event generated by the server.

Parameters

hServer

The server handle. The application should treat this as an opaque value that is only valid as long as the server is active. This value should not be stored by the application and the handle value will change if the server is restarted.

nClientId

An unsigned integer which uniquely identifies the client that has issued a request to the server. This value is guaranteed to be unique to the client session throughout the life of the server and is never reused. The application should never make assumptions about the order in which IDs are allocated to the client sessions.

nEventId

An unsigned integer which specifies which event occurred. For a list of events, see [Server Event Constants](#).

dwError

An unsigned integer which specifies any error that occurred. If no error occurred, then this parameter will be zero.

bHandled

An integer which specifies if the event has been handled by the application. If this parameter is set to a non-zero value, the default event handler will not be invoked for the event.

Return Value

The method should return a value of zero to indicate that the default event handler should be invoked for the event. If the method returns a non-zero value, this value is passed back to the event dispatcher and the default handler will not be invoked.

Remarks

The **PreProcessEvent** method is invoked for each event that is generated, prior to the default handler for that event. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

CHttpServer::ReceiveRequest Method

```
BOOL ReceiveRequest(  
    UINT nClientId,  
    DWORD dwOptions,  
    LPHTTPREQUEST LpRequest,  
    LPVOID LpvBuffer,  
    LPDWORD LpdwLength  
);
```

Receive the request that was sent by the client to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwOptions

An unsigned integer which specifies how the client request data will be copied. It may be one of the following values:

Value	Description
HTTP_REQUEST_DEFAULT	If the <i>lpdwLength</i> parameter points to a integer with a non-zero value, the <i>lpvBuffer</i> parameter is considered to be a pointer to a block of memory that has been allocated to store the request data. This is the same as specifying the HTTP_REQUEST_MEMORY option. If the <i>lpdwLength</i> parameter points to an integer with a value of zero, the <i>lpvBuffer</i> parameter is considered to be a pointer to an HGLOBAL memory handle. This is the same as specifying the HTTP_REQUEST_HGLOBAL option.
HTTP_REQUEST_MEMORY	The <i>lpvBuffer</i> parameter is a pointer to a block of memory that has been allocated to store the request data. The maximum number of bytes of data that can stored is determined by the value of the integer that the <i>lpdwLength</i> parameter points to. When the method returns, that value will updated with with actual number of bytes copied into the buffer.
HTTP_REQUEST_STRING	The <i>lpvBuffer</i> parameter is a pointer to a string buffer that has been allocated to store the request data. The maximum number of bytes of data that can stored is determined by the value of the integer that the <i>lpdwLength</i> parameter points to. When the method returns, that value will updated with with actual number of bytes copied into the buffer.
HTTP_REQUEST_HGLOBAL	The <i>lpvBuffer</i> parameter is a pointer to an HGLOBAL memory handle. When the method returns, the handle will reference a block of memory that contains the request data submitted by the client. The <i>lpdwLength</i> parameter will contain the number of bytes copied to the buffer.
HTTP_REQUEST_FILE	The <i>lpvBuffer</i> parameter is a pointer to a string which

	specifies the name of a file that will contain the request data. If the file does not exist, it will be created. If it does exist, the contents will be replaced. This option is typically used in conjunction with the PUT command. If the <i>lpdwLength</i> parameter is not NULL, the value it points to will be updated with the actual number of bytes stored in the file.
HTTP_REQUEST_HANDLE	The <i>lpvBuffer</i> parameter is a handle to an open file. This option is typically used in conjunction with the POST or PUT commands. If the <i>lpdwLength</i> parameter is not NULL, the value it points to will be updated with the actual number of bytes written to the file. If this option is specified, the request data will be written from the current position in the file and will advance the file pointer by the number of bytes received from the client.

lpRequest

A pointer to a **HTTPREQUEST** structure which contains information about the request from the client. This parameter cannot be NULL. The structure that is passed to this method must have all members set to a value of zero except the *dwSize* member, which must be initialized to the size of the structure.

lpvBuffer

A pointer to the buffer that will contain any request data that was submitted by the client. The *dwOptions* parameter determines if this pointer references a block of memory, a null-terminated string buffer, a global memory handle or a file name. If this parameter is NULL, any data submitted by the client will not be copied.

lpdwLength

A pointer to an unsigned integer that will contain the number of bytes of data submitted by the client when the method returns. If the *lpvBuffer* parameter specifies a memory or string buffer, this value must be initialized to the maximum size of the buffer before the method is called. If the *lpvBuffer* parameter points to a global memory handle, this value must be initialized to zero. If *lpvBuffer* is NULL or specifies a file name, this parameter may be NULL.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **ReceiveRequest** method is called within an **OnCommand** event handler to process the command issued by the client and return information about the request to the server application. It is only necessary for the application to call this method if it wants to implement its own custom handling for a command. It is recommended that most applications use the default command processing for standard commands such as GET and POST to ensure that the appropriate security checks are performed and the response conforms to the protocol standard.

This method may only be called once per command issued by the client and the data referenced in the **HTTPREQUEST** structure only remains valid while the client is connected to the server. You should never attempt to directly modify the data referenced by any of the structure members. If you wish to store or modify any of the string values returned in the structure, you should allocate a buffer large enough to store the contents of the string, including the terminating null character, and copy the string into that buffer.

If the HTTP_REQUEST_HGLOBAL option is used to return a copy of the request data in a global memory buffer, the HGLOBAL handle must be freed by the application when the data is no longer needed. Failure to free this handle will result in a memory leak.

If the HTTP_REQUEST_HANDLE option is used to write a copy of the request data to an open file, the handle must reference a disk file that was opened or created using the **CreateFile** function with GENERIC_WRITE access. It cannot be a handle to a device or named pipe. If the method succeeds, the file pointer is advanced by the number of bytes of request data submitted by the client. If the method fails, the file pointer is returned to its original position prior to the method being called.

Example

```
// Initialize the HTTPREQUEST structure
HTTPREQUEST httpRequest;
ZeroMemory(&httpRequest, sizeof(httpRequest));
httpRequest.dwSize = sizeof(httpRequest);

// Return the data in a global memory buffer
HGLOBAL hgb1Buffer = NULL;
DWORD dwLength = 0;

bSuccess = pServer->ReceiveRequest(nClientId,
                                   HTTP_REQUEST_HGLOBAL,
                                   &httpRequest,
                                   &hgb1Buffer,
                                   &dwLength);

if (bSuccess && hgb1Buffer != NULL)
{
    LPBYTE lpBuffer = (LPBYTE)GlobalLock(hgb1Buffer);

    if (lpBuffer != NULL)
    {
        // Process dwLength bytes of data submitted by the client
    }

    GlobalUnlock(hgb1Buffer);
    GlobalFree(hgb1Buffer);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

[SendResponse](#), [HTTPREQUEST](#)

CHttpServer::RedirectRequest Method

```
BOOL RedirectRequest(  
    UINT nClientId,  
    UINT nMethod,  
    LPCTSTR lpszLocation  
);
```

Redirect the request from the client to another URL.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nMethod

An integer value that specifies if the redirection is permanent or temporary. The following values may be used:

Value	Description
HTTP_REDIRECT_PERMANENT	This value is used for permanent redirection, indicating that the client should update any record of the link with the new URL specified by the <i>lpszLocation</i> parameter. This result is cacheable and when the client makes subsequent requests for the resource, it should always use the new URL.
HTTP_REDIRECT_TEMPORARY	This value is used for temporary redirection, indicating that the client should issue a request for the resource using the new URL specified by the <i>lpszLocation</i> parameter, but subsequent requests should continue to use the original URL.
HTTP_REDIRECT_OTHER	This value is used for temporary redirection, however it instructs the client that it should use the GET command to request the redirected resource. This option is typically used to redirect a client after it has used the POST command.

lpszLocation

A pointer to a string that specifies the new location for the requested resource. This value must be a complete URL, including the http:// or https:// scheme. This parameter cannot be NULL or point to zero-length string.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **RedirectRequest** method can be used within a HTTP_CLIENT_COMMAND event handler to redirect the client to a new location for the resource that it has requested. This redirection can be permanent or temporary, depending on whether the server expects the client to continue to use the original URL when requesting the resource.

If the HTTP_REDIRECT_TEMPORARY method is used, the actual status code that is returned to the client depends on the version of the protocol that is being used. If the client has issued the request using HTTP 1.0 then the server will return a 302 code to the client. If the client is using HTTP 1.1, the server will return a 307 code to the client that indicates it should use the same command verb (GET, POST, etc.) when requesting the resource at the new location.

If the HTTP_REDIRECT_OTHER method is used, the status code that is returned to the client depends on which version of the protocol is being used. For clients who are using HTTP 1.0, the server will return a 302 code to the client just as with the HTTP_REDIRECT_TEMPORARY method. If the client is using HTTP 1.1, the server will return a 303 code to the client that indicates it should always use the GET command to request the new resource, regardless if a different command was originally used (POST, PUT, etc.)

This method provides a simplified interface for sending a redirection status code that also implicitly sets the Location response header to the value of the *lpzLocation* parameter. If the server application needs to send alternate redirection codes such as 305 (Use Proxy) then it should use the **SendResponse** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::RegisterHandler Method

```
BOOL RegisterHandler(  
    UINT nHostId,  
    LPCTSTR lpszExtension,  
    LPCTSTR lpszProgramFile,  
    LPCTSTR lpszParameters,  
    LPCTSTR lpszDirectory  
);
```

Register a CGI program for use and associate it with a file name extension.

Parameters

nHostId

An unsigned integer that identifies the virtual host associated with the program. The value VIRTUAL_HOST_DEFAULT should be used for the default host that is created when the server is first started.

lpszExtension

A pointer to a string which specifies the file name extension that is associated with the CGI program. This parameter cannot be NULL.

lpszProgramFile

A pointer to a string that specifies the full path to the executable program. This parameter cannot be NULL.

lpszParameters

A pointer to a string that specifies additional parameters for the program. This value will be passed to the program as command line arguments. If the program does not require any command line parameters, this value may be NULL or point to an empty string.

lpszDirectory

A pointer to a string that specifies the current working directory for the program. If this parameter is NULL or points to an empty string, the server will use the root document directory for the virtual host.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **RegisterHandler** method registers an executable CGI program and associates it with a file name extension. When the client issues a GET or POST command that specifies a file with that extension, the program will be executed and the output return to the client.

The *lpszProgramFile* string specifies file name of the CGI program. You should not install any executable programs in the server root directory or its subdirectories. A client should never have the ability to directly access the executable file itself. It is permitted to have multiple file name extensions that reference the same program. The only requirement is that the extension be unique for the given host. The program name may contain environment variables surrounded by % symbols. For example, %ProgramFiles% would be expanded to the **C:\Program Files** folder.

It is important to note that the program specified by *lpszProgramFile* must be an executable file, not a script or batch file. If the program name does not contain a directory path, then the standard

Windows pathing rules will be used when searching for an executable file that matches the given name. It is recommended that you always provide a full path to the executable file.

The *lpszParameters* string can specify additional command line parameters that should be passed to the CGI program as arguments. This string can also contain a placeholder named "%1" that will be replaced by the full path to the local script filename. If no placeholder is included in the parameters, or *lpszParameters* is a NULL pointer, the script file name will be passed to the program as its only argument.

The executable program that is registered using this program must be a console application that conforms to the CGI/1.1 specification defined in RFC 3875. Request data submitted by the client as part of a POST will be provided to the program as standard input. The output from the program must be written to standard output. The first lines of output from the program should be any response headers, followed by an empty line. Each line should be terminated with a carriage-return and linefeed (CRLF) sequence. If the CGI program outputs additional data to be processed by the client, it should provide Content-Type and Content-Length response headers.

The application can obtain a copy of the output from the command by calling the **GetProgramOutput** method from within an **OnExecute** event handler.

When developing a CGI program, it is important to take into consideration the environment that it will be executing in. The program will be started as a child process of the server application, and will inherit the same privileges. This means that it will typically have access to the boot drive, the Windows folders and the system registry. CGI programs must ensure that all query parameters and request data submitted by the client have been validated.

If the server is running on a system with User Account Control (UAC) enabled and does not have elevated privileges, do not register a program that requires elevated privileges or has a manifest that specifies the requestedExecutionLevel as requiring administrative privileges.

Example

```
// Register a handler for VBScript
pServer->RegisterHandler(hServer,
                        VIRTUAL_HOST_DEFAULT,
                        _T("vbs"),
                        _T("%SystemRoot%\\System32\\cscript.exe"),
                        _T("/nologo /b \"%1\""),
                        NULL);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::RegisterProgram Method

```
BOOL RegisterProgram(  
    LPCTSTR lpszVirtualPath,  
    LPCTSTR lpszProgramFile,  
);
```

```
BOOL RegisterProgram(  
    LPCTSTR lpszVirtualPath,  
    LPCTSTR lpszProgramFile,  
    LPCTSTR lpszParameters,  
    LPCTSTR lpszDirectory  
);
```

Register a CGI program for use and associate it with a virtual path on the server.

Parameters

nHostId

An unsigned integer that identifies the virtual host associated with the program. The value `VIRTUAL_HOST_DEFAULT` should be used for the default host that is created when the server is first started.

lpszVirtualPath

A pointer to a string which specifies the virtual path to the CGI program. This must be an absolute path, but does not have to specify a pre-existing virtual path or map to the directory structure of the root document directory for the server. This parameter cannot be NULL. The maximum length of the virtual path is 1024 characters.

lpszProgramFile

A pointer to a string that specifies the full path to the executable program. This parameter cannot be NULL.

lpszParameters

A pointer to a string that specifies additional parameters for the program. This value will be passed to the program as command line arguments. If the program does not require any command line parameters, this value may be NULL or point to an empty string.

lpszDirectory

A pointer to a string that specifies the current working directory for the program. If this parameter is NULL or points to an empty string, the server will use the root document directory for the virtual host.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value will be zero and the **GetLastError** method can be used to retrieve the last error code.

Remarks

The **RegisterProgram** function registers an executable CGI program and associates it with a virtual path. When the client issues a GET or POST command specifying the virtual path associated with the program, the program will be executed and the output return to the client.

The *lpszProgramFile* string specifies file name of the CGI program. You should not install any executable programs in the server root directory or its subdirectories. A client should never have the ability to directly access the executable file itself. It is permitted to have multiple virtual paths that

reference the same executable file. The only requirement is that the virtual path be unique for the given host. The program name may contain environment variables surrounded by % symbols. For example, %ProgramFiles% would be expanded to the **C:\Program Files** folder.

It is important to note that the program specified by *lpzProgramFile* must be an executable file, not a script or batch file. If the program name does not contain a directory path, then the standard Windows pathing rules will be used when searching for an executable file that matches the given name. It is recommended that you always provide a full path to the executable file.

The *lpzParameters* string can specify additional command line parameters that should be passed to the CGI program as arguments. This string can also contain a placeholder named "%1" that will be replaced by the virtual path associated with the program. If *lpzParameters* is NULL or a zero-length string, then no additional parameters are passed to the program.

The executable program that is registered using this program must be a console application that conforms to the CGI/1.1 specification defined in RFC 3875. Request data submitted by the client as part of a POST will be provided to the program as standard input. The output from the program must be written to standard output. The first lines of output from the program should be any response headers, followed by an empty line. Each line should be terminated with a carriage-return and linefeed (CRLF) sequence. If the CGI program outputs additional data to be processed by the client, it should provide Content-Type and Content-Length response headers.

The application can obtain a copy of the output from the command by calling the **GetProgramOutput** function from within an **OnExecute** event handler.

When developing a CGI program, it is important to take into consideration the environment that it will be executing in. The program will be started as a child process of the server application, and will inherit the same privileges. This means that it will typically have access to the boot drive, the Windows folders and the system registry. CGI programs must ensure that all query parameters and request data submitted by the client have been validated.

If the server is running on a system with User Account Control (UAC) enabled and does not have elevated privileges, do not register a program that requires elevated privileges or has a manifest that specifies the requestedExecutionLevel as requiring administrative privileges.

Example

```
m_pServer->RegisterProgram(hServer,
                           VIRTUAL_HOST_DEFAULT,
                           HTTP_METHOD_DEFAULT,
                           _T("/order/invoice"),
                           _T("%ProgramData%\MyServer\Programs\invoice.exe"),
                           NULL,
                           NULL);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetProgramExitCode](#), [GetProgramOutput](#), [RegisterHandler](#)

CHttpServer::RenameServerLogFile Method

```
BOOL RenameServerLogFile(  
    LPCTSTR lpszFileName  
);
```

Rename or delete the current log file being updated by the server.

Parameters

lpszFileName

A pointer to a string that specifies the file name the current log file should be renamed to. If this parameter is NULL or an empty string, the current log file will be deleted.

Return Value

If the method succeeds, the return value is non-zero. If logging is not currently enabled for the server, this method will return zero.

Remarks

The **RenameServerLogFile** method is used to rename or delete the current log file. Note that this does not change the current log file name or disable logging by the server. It only changes the file name of the current log file, or removes the log file if the *lpszFileName* parameter is NULL. This can be useful if you want your server to perform log file rotation, archiving the current log file. By renaming the current log file, the server will automatically create a new log file with original file name.

This method must be used to rename or delete the current log file while logging is active because the server holds an open handle on the file. The application should not use the **GetLogFile** method to obtain the log file name and then use the **MoveFileEx** or **DeleteFile** Windows API functions with that file.

To disable logging, use the **SetLogFile** method and specify the logging format as HTTP_LOGFILE_NONE.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetLogFile](#), [SetLogFile](#)

CHttpServer::RequireAuthentication Method

```
BOOL RequireAuthentication(  
    UINT nClientId,  
    UINT nAuthType,  
    LPCTSTR lpszRealm  
);
```

Send a response to the client indicating that authentication is required.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nAuthType

An integer value that corresponds to a result code, informing the client if the redirection is permanent or temporary. The following values may be used:

Value	Description
HTTP_AUTH_BASIC	This option specifies the Basic authentication scheme should be used. This option is supported by all clients that support at least version 1.0 of the protocol.

lpszRealm

A pointer to a string that is displayed by a web browser to indicate to the user which username and password they should use. If this parameter is NULL or an empty string, the domain name the client used to establish the connection will be used.

Return Value

If the function succeeds, the return value is non-zero. If the function fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **RequireAuthentication** method can be used within an **OnCommand** event handler to indicate to the client that it must provide a username and password to access the requested resource. The client should respond by issuing another request that includes the required credentials. To determine if a client has included credentials with its request, use the **IsClientAuthenticated** method. The **GetClientCredentials** method will return the username and password that was provided by the client.

Some clients may require that the session be secure if authentication is requested or display warning messages to the user if the connection is not secure. It is recommended that you enable security using the HTTP_OPTION_SECURE option if your application will require clients to authenticate before accessing specific resources.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h
- Import Library:** cshtsv11.lib
- Unicode:** Implemented as Unicode and ANSI versions

See Also

CHttpServer::Restart Method

BOOL Restart();

Restart the server, terminating all active client sessions.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Restart** method will restart the specified server, terminating all active client sessions. If the method is unable to restart the server for any reason, the server thread is terminated. The server retains all of the configuration parameters from the previous instance, however the statistical information (such as the number of clients, files transferred, etc.) will be reset.

If an application calls this method from within an event handler, the active client session (the client for which the event handler was invoked) may not get a disconnect notification. It is recommended that this method only be called by the same thread that created the server using the **Start** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[Start](#), [Stop](#)

CHttpServer::Resume Method

BOOL Resume();

Resume accepting client connections.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Resume** method instructs the server to resume accepting new client connections after the **Suspend** method has been called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

[Restart](#), [Start](#), [Stop](#), [Suspend](#), [Throttle](#)

CHttpServer::SendErrorResponse Method

```
BOOL SendErrorResponse(  
    UINT nClientId,  
    UINT nErrorCode,  
    LPCTSTR lpszMessage  
);
```

Send a customized error response to the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nErrorCode

An integer value that specifies the error code that should be sent to the client. This value should correspond to the error result codes defined for HTTP in RFC 2616, which are three-digit values in the range of 400 through 599. The method will fail if an invalid error code is specified.

lpszMessage

A pointer to a string that describes the error. If this parameter is NULL or specifies a zero-length string, a default message will be selected based on the error code.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **SendErrorResponse** method sends a response to the client indicating that an error has occurred, providing a numeric error code and HTML formatted text which may be displayed to the user. The *lpszMessage* parameter should provide a brief description of the error that will be included in the output sent to the client. Note that the message should not contain any special formatting control characters or HTML markup.

This method provides a simplified interface for sending an error response to the client. In some cases, a browser may choose to display its own error message to the user in place of the generic HTML document generated by this method. If you want your application to send a customized HTML document for a specific type of error, you should use the **SendResponse** method.

If you wish to redirect the client to use an alternate URL to access the requested resource, it is recommended that you use the **RedirectRequest** method rather than sending an error response.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[RedirectRequest](#), [SendResponse](#)

CHttpServer::SendResponse Method

```
BOOL SendResponse(  
    UINT nClientId,  
    DWORD dwOptions,  
    LPHTTPRESPONSE lpResponse,  
    LPVOID lpvBuffer,  
    DWORD dwLength  
);
```

Send a response from the server to the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwOptions

An unsigned integer which specifies how the client request data will be copied. It may be one of the following values:

Value	Description
HTTP_RESPONSE_DEFAULT	The <i>lpvBuffer</i> parameter is a pointer to a block of memory that contains the response data. The number of bytes of data that in the buffer is specified by the <i>dwLength</i> parameter. This is the same as specifying the HTTP_RESPONSE_MEMORY option.
HTTP_RESPONSE_MEMORY	The <i>lpvBuffer</i> parameter is a pointer to a block of memory that contains the response data. The number of bytes of data that in the buffer is specified by the <i>dwLength</i> parameter. The data will be sent to the client as a stream of bytes. If the server application was compiled using Unicode, it is responsibility of the application to convert any Unicode text to either ANSI or UTF-8, depending on the resource that was requested by the client.
HTTP_RESPONSE_STRING	The <i>lpvBuffer</i> parameter is a pointer to a string buffer that contains the response data. The maximum number of bytes of data that will be sent to the client is determined by the <i>dwLength</i> parameter. If the value of the <i>dwLength</i> parameter exceeds the string length, the value will be ignored and the contents of the string will be sent up to the terminating null character. If the Unicode version of this method is called, the string will be converted to a byte array before being sent to the client.
HTTP_RESPONSE_HGLOBAL	The <i>lpvBuffer</i> parameter is an HGLOBAL memory handle which references a block of memory that contains the response data. The number of bytes of data that in the buffer is specified by the <i>dwLength</i> parameter. The data will be sent to the client as a stream of bytes. It is the responsibility of the application to free the global memory

	handle after it is no longer needed.
HTTP_RESPONSE_FILE	The <i>lpvBuffer</i> parameter is a pointer to a string which specifies the name of a file that contains the response data. If the file does not exist, or does not specify a regular file, this method will fail. The <i>dwLength</i> parameter is ignored. If the content type for the specified file is not explicitly defined in the response, the method will attempt to automatically determine the correct type based on the file name extension and/or the contents of the file.
HTTP_RESPONSE_HANDLE	The <i>lpvBuffer</i> parameter is a handle to an open file and the <i>dwLength</i> parameter specifies the number of bytes to be read from the file and send to the client. If this option is specified, the response data will be read from the current position in the file and will advance the file pointer by the number of bytes sent to the client.
HTTP_RESPONSE_DYNAMIC	The response data will be generated dynamically. This prevents the content length from being included in the response header, and forces the connection to close, regardless if the keep-alive option has been specified. This option must be specified if the application wishes to use the SendResponseData method to send additional data to the client.
HTTP_RESPONSE_NOCACHE	Informs the client that the data being returned by the server should not be cached. Typically this is used in conjunction with the HTTP_RESPONSE_DYNAMIC option when the data is being generated dynamically.

lpResponse

A pointer to a **HTTPRESPONSE** structure which contains additional information about the response to the client. The structure that is passed by reference to this method must have the *dwSize* member initialized to the size of the structure or the method will fail. This parameter may be NULL, in which case a default response of "200 OK" is sent to the client along with any data specified by the *lpvBuffer* parameter.

lpvBuffer

A pointer to the buffer that will contain any response data that should be sent to the client. The *dwOptions* parameter determines if this pointer references a block of memory, a null-terminated string buffer, a global memory handle or a file name. This parameter may be NULL, in which case no data will be sent to the client. If this method is called in response to a HEAD command being sent by the client, this parameter is ignored.

dwLength

An unsigned integer that specifies the number of bytes of data to be sent to the client. If the *lpvBuffer* parameter is NULL, this value must be zero. If this method is called in response to a HEAD command being sent by the client, this parameter is ignored.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

The **SendResponse** method is called within an **OnCommand** event handler to respond to the request made by the client. This method may only be called once after a command has been received, and must be called after the **ReceiveRequest** method. It is only necessary for the application to call this method if it wants to implement its own custom handling for a command. It is recommended that most applications use the default command processing for standard commands such as GET and POST to ensure that the appropriate security checks are performed and the response conforms to the protocol standard.

If the HTTP_RESPONSE_HANDLE option is used to read a copy of the response data from an open file, the handle must reference a disk file that was opened using the **CreateFile** function with GENERIC_READ access. It cannot be a handle to a device or named pipe. If the *dwLength* parameter is larger than the total number of bytes available to be read from the current position in the file, the method will stop sending data to the client when it reaches the end-of-file. If the method succeeds, the file pointer is advanced by the number of bytes of response data sent to the the client. If the method fails, the file pointer is returned to its original position prior to the method being called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::SendResponseData Method

```
INT SendResponseData(  
    UINT nClientId,  
    LPBYTE lpBuffer,  
    INT nLength  
);
```

Send additional data to the client in response to a command.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpBuffer

A pointer to a buffer that contains the response data that should be sent to the client. This parameter cannot be NULL.

nLength

An integer that specifies the number of bytes of data in the buffer. This value must be greater than zero.

Return Value

If the method succeeds, the return value is the number of bytes of data sent to the client. If the method fails, the return value is HTTP_ERROR. To get extended error information, call the **GetLastError** method.

Remarks

The **SendResponseData** method is called within a **OnCommand** event handler to send data to the client in response to a request. This method can only be used to send dynamically generated content after the **SendResponse** method has been called. The HTTP_RESPONSE_DYNAMIC option must have been specified when responding to the client or this method will fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[RecieveRequest](#), [SendResponse](#), [OnCommand](#), [HTTPRESPONSE](#)

CHttpServer::SetCertificate Method

```
BOOL SetCertificate(  
    DWORD dwProtocol,  
    LPCTSTR lpszCertStore,  
    LPCTSTR lpszCertName,  
    LPCTSTR lpszPassword  
);  
  
BOOL SetCertificate(  
    LPCTSTR lpszCertName,  
    LPCTSTR lpszPassword  
);
```

Set the name of the certificate to be used with secure connections.

Parameters

dwProtocol

A bitmask of supported security protocols. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.

SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

lpszCertStore

A pointer to a string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The function will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the function will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the function will return an error indicating that the certificate could not be found.

lpszPassword

An optional pointer to a string which specifies the certificate owner's password. A value of NULL specifies that no password is required. This parameter is only required if the *lpszCertStore* parameter specifies a certificate file in PKCS #12 format that is password protected.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

An application only needs to call this method to support secure connections using TLS. When a certificate is specified, it must have a private key associated with it. Attempting to use a certificate which does not have a private key will result in an error during the startup process indicating that the server credentials are invalid.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user, or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *lpzCertStore* parameter should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. If a password was specified when the certificate was created, it must be provided in the *lpzPassword* parameter or the class will be unable to access the certificate.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetOptions](#), [SetOptions](#)

CHttpServer::SetClientAccess Method

```
BOOL SetClientAccess(  
    UINT nClientId,  
    DWORD dwUserAccess  
);
```

Change the access rights associated with the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

dwUserAccess

An unsigned integer which specifies one or more user access rights. For a list of user access rights that can be granted to the client, see [User and File Access Constants](#).

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. This method can only be used with authenticated clients. If the client session has not been authenticated, the return value will be zero.

Remarks

The **SetClientAccess** method can change multiple access rights for the client session. The **EnableClientAccess** method can be used to grant or revoke a specific permission for the client session.

If the *dwUserAccess* parameter has a value of HTTP_ACCESS_DEFAULT, then default permissions will be granted to the client session based on the configuration of the server. This is the recommended value for most clients. It is important to consider the implications of changing the access permissions granted to a client session. For example, if you do not grant clients HTTP_ACCESS_READ permission, it can effectively disable the site because the server will return 403 Forbidden errors for all GET and HEAD requests.

This function should typically be called in the **OnConnect** event handler to assign general permissions to the client, or in the **OnCommand** event handler after the client has issued a request and provided any authentication credentials that are required.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[AuthenticateClient](#), [EnableClientAccess](#), [GetClientAccess](#)

CHttpServer::SetClientHeader Method

```
BOOL HttpSetClientHeader(  
    UINT nClientId,  
    UINT nHeaderType,  
    LPCTSTR lpszHeaderName,  
    LPCTSTR lpszHeaderValue  
);
```

Create or change the value of a request or response header for the client session.

Parameters

nClientId
An unsigned integer which uniquely identifies the client session.

nHeaderType
Specifies the type of header to create or modify. It may be one of the following values:

Value	Description
HTTP_HEADERS_REQUEST	Change a request header that was provided by the client. Request header values provide additional information to the server about the type of request being made.
HTTP_HEADERS_RESPONSE	Change a response header that was created by the server. Response header values provide additional information to the client about the type of information that is being returned by the server.

lpszHeaderName
A pointer to a string that specifies the name of the header that should be created or modified. Header names are not case-sensitive and should not include the colon which acts as a delimiter that separates the header name from its value. This parameter cannot be a NULL pointer or an empty string.

lpszHeaderValue
A pointer to a string that specifies the new value of the header. If this parameter is a NULL pointer or an empty string, it has the same effect as deleting the header value from the list of request or response headers.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **SetClientHeader** method will change the value of a request or response header for the specified client session. If the *lpszHeaderName* value matches an existing header field, its value will be replaced. If the header name is not defined, then a new header will be created with the given value. You should not change the value of most standard response header values unless you are certain of the impact that it would have on the normal operation of the client.

If you wish to define a custom header value that would be included in the response to a client request, you should prefix the header name with "X-" to avoid potential conflicts with the standard response

headers. For example, if you wanted to identify a customer, you could create a header field with the name "X-Customer-ID" and set the value to the customer ID number. The client application would receive this custom header value as part of the response to its request for a document.

Refer to [Hypertext Transfer Protocol Headers](#) for a list of common request and response headers that are used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DeleteClientHeader](#), [GetClientHeader](#)

CHttpServer::SetClientIdleTime Method

```
UINT SetClientIdleTime(  
    UINT nClientId,  
    UINT nTimeout  
);
```

Change the idle timeout period for the specified client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nTimeout

An unsigned integer value that specifies the number of seconds that the client may remain idle. If this value is zero, the default idle timeout period for the server will be used.

Return Value

If the method succeeds, the return value is the previous client idle timeout period in seconds. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **SetClientIdleTime** method will change the number of seconds that the client may remain idle before being automatically disconnected by the server. The minimum timeout period for a client is 10 seconds, the maximum is 300 seconds (5 minutes). The idle time of a client session is based on the last time a command was issued to the server or when a data transfer completed.

If the value INFINITE is specified as the timeout period, the client activity timer will be refreshed, extending the idle timeout period for the session. This is typically done inside an **OnTimeout** event handler to prevent the client from being disconnected due to inactivity.

To obtain the current idle timeout period for a client, along with the amount of time the client has been idle, use the **GetClientIdleTime** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[GetClientIdleTime](#)

CHttpServer::SetClientVariable Method

```
BOOL HttpSetClientVariable(  
    UINT nClientId,  
    LPCTSTR lpszName,  
    LPCTSTR lpszValue  
);
```

Create or change the value of a CGI environment variable for the specified client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszName

A pointer to a string that specifies the name of the environment variable that should be created or modified. Environment variables are not case-sensitive and should not include the equal sign which acts as a delimiter that separates the variable name from its value. This parameter cannot be a NULL pointer or an empty string.

lpszValue

A pointer to a string that specifies the new value of the environment variable. If this parameter is a NULL pointer or an empty string, it has the same effect as deleting the variable from the environment block for the client session.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero. If the method fails, the **GetLastError** method will return more information about the last error that has occurred.

Remarks

The **SetClientVariable** method will change the value of a environment variable for the specified client session. If the *lpszName* value matches an existing variable, its value will be replaced. If the variable is not defined, then a new variable will be created with the given value. The value of an environment variable can be obtained using the **GetClientVariable** method.

The server will automatically create a number of different environment variables that will be passed to a program or script executed by the server. These variables are defined in RFC 3875 as part of the Common Gateway Interface (CGI) 1.1 specification. The following variables are defined by the server and should not be modified directly by the application:

Variable Name	Description
AUTH_TYPE	The authorization scheme used by the server to authenticate the client session
CONTENT_LENGTH	The length of the request data provided by the client
CONTENT_TYPE	The MIME type that identifies the type of content provided by the client
DOCUMENT_ROOT	The full path to the local document root directory on the server
GATEWAY_INTERFACE	The version of the Common Gateway Interface that is being used by the server
PATH_INFO	The resource or sub-resource that is to be returned by the program or

	script
PATH_TRANSLATED	The path information mapped to the server root document directory structure
QUERY_STRING	The URL encoded query parameters passed to the program or script
REMOTE_ADDR	The network address of the client sending the request to the server
REMOTE_HOST	The same value as the REMOTE_ADDR variable
REMOTE_USER	The username specified as part of the authentication credentials provided by the client
REQUEST_METHOD	The method used by the client to request the resource
REQUEST_URI	The URI for the script provided by the client
SCRIPT_FILENAME	The full path to the program or script on the server
SCRIPT_NAME	The path to the program or script specified by the client
SERVER_NAME	The hostname or IP address of the server that the client connected to
SERVER_PORT	The port number that the client used to connect to the server
SERVER_PORT_SECURE	This variable has a value of "1" if the client connection to the server is secure
SERVER_PROTOCOL	The version of the server protocol used
SERVER_SOFTWARE	The server identity string which specifies the application name and version

In addition to the environment variables listed, the server will also create variables that are prefixed with "HTTP_" that are set to the value of request headers that are not otherwise defined. For example, the HTTP_USER_AGENT variable will be set to the value of the User-Agent header provided by the client as part of the request.

Calling the **SetClientVariable** method within an **OnExecute** event handler will have no effect because it occurs after the CGI program or script has completed execution. To create or modify environment variables for the client session, it should be done within an **OnCommand** event handler.

This method will not change the environment block for the server process. Each client session is allocated its own private environment block which is inherited by the CGI program. When the client session terminates, the memory allocated for its environment is released.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetClientVariable](#)

CHttpServer::SetCommandFile Method

```
BOOL SetCommandFile(  
    UINT nClientId,  
    LPCTSTR lpszFileName  
);
```

Change the name of a file or directory that is the target of the current command.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the new file name. This parameter may be NULL to specify that the original file or directory name should be used.

Return Value

If the method succeeds, the return value is non-zero. If the client ID does not specify a valid client session, the method will return zero.

Remarks

The **SetCommandFile** method is used by the application to change the target file or directory name for the current command from within an **OnCommand** event handler. This can be used to effectively redirect the client to use a different file than the one that was actually requested. For example, if the client issues the GET command to download a file from the server, this method can be used to redirect the command to use a different file name. To obtain the full path to the file or directory that is the target of the current command, use the **GetCommandFile** method.

The *lpszFileName* parameter specifies the path to the new file or directory name. If the path is absolute, then it will be used as-is. If the path is relative, it will be relative to the root directory for the client session. Because the root document directory for the client can depend on the hostname that the client used when connecting to the server, it is recommended that you always use an absolute path. The full path to this file is not limited to the server root directory or its subdirectory, it can specify a file anywhere on the local system. If this parameter is a NULL pointer, or points to an empty string, then the server will revert to using the actual file or directory name specified by the command. This enables the application to effectively undo a previous call to this method to change the target file name.

Typically this method would be used to redirect a client to a file or directory that it may not normally have access to. Exercise caution when using this method to provide access to data that is stored outside of the server root directory. Incorrect use of this method could expose the server to security risks or cause unpredictable behavior by client applications. In most cases it is preferable to use the **AddVirtualPath** method to create a virtual path or file name on the server, or the **RedirectRequest** method to request the client use a different URL to access the resource.

This method should only be called within the context of the **OnCommand** event, and only for those commands that perform an action on a file or directory. If the current command does not target a file or directory, this method will return zero and the last error code will be set to ST_ERROR_INVALID_COMMAND.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CHttpServer::SetDirectory Method

```
BOOL SetDirectory(  
    LPCTSTR lpszDirectory  
);
```

Specify the local directory that will be used as the server root directory.

Parameters

lpszDirectory

A pointer to a string that specifies the root directory for the server. If this parameter is NULL or a zero-length string, the server will use the current working directory as the root directory.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, it will return zero.

Remarks

The **SetDirectory** method specifies the path to the local directory that should be used as the root document directory for the server.

You cannot change the server root directory after the server has started. To change the root directory, you must stop the server using the **Stop** method and then start another instance of the server with a configuration that specifies the new directory.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetDirectory](#)

CHttpServer::SetIdentity Method

```
BOOL SetIdentity(  
    LPCTSTR lpszIdentity  
);
```

Change the identity of the specified server.

Parameters

lpszIdentity

A pointer to a string that identifies the server. If this parameter is NULL or specifies an empty string, the current identity for the server is reset to a default value. The maximum length of the identity string is 64 characters, including the terminating null character.

Return Value

If the method succeeds, the return value is non-zero, otherwise it will return a value of zero.

Remarks

The **SetClientIdentity** method changes a string value used by the server to identify itself to clients. The identity string does not have any standard format and is used for informational purposes only. Typically it consists of the application name and a version number. Changing the server identity has no effect on the operation of the server. To obtain the identity string currently associated with the server, use the **GetIdentity** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetIdentity](#)

CHttpServer::SetLastError Method

```
VOID SetLastError(  
    DWORD dwError  
);
```

Set the last error code for the specified server session.

Parameters

dwError

An unsigned integer that specifies an error code.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each server session. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_SERVER or HTTP_ERROR.

If the *dwError* parameter is specified with a value of zero, this effectively clears the error code for the last method that failed. Those methods which clear the last error code when they succeed are noted on their reference page.

Applications can retrieve the value saved by this method by calling the **GetLastError** method to determine the specific reason for failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[GetCommandResult](#), [GetLastError](#), [SendResponse](#)

CHttpServer::SetLogFile Method

```
BOOL SetLogFile(  
    UINT nLogFormat,  
    UINT nLogLevel,  
    LPCTSTR lpszFileName  
);
```

Change the current log format, level of detail and file name.

Parameters

nLogFormat

An integer value that specifies the format used when creating or updating the server log file. The following formats are supported:

Value	Description
HTTP_LOGFILE_NONE	This value specifies that the server should not create or update a log file.
HTTP_LOGFILE_COMMON	This value specifies that the log file should use the common log format that records a subset of information in a fixed format. This log format usually only provides information about GET, PUT and POST requests.
HTTP_LOGFILE_COMBINED	This value specifies that the server should use the combined log file format. This format is similar to the common format, however it includes the client referrer and user agent. This is the format that most Apache web servers use by default.
HTTP_LOGFILE_EXTENDED	This value specifies that the log file should use the standard W3C extended log file format. This is an extensible format that can provide additional information about the client session. This format typically generates the largest logfiles.

nLogLevel

An integer value that specifies the level of detail that should generated in the log file. The minimum value is 1 and the maximum value is 10. If this parameter is zero, it is the same as specifying a log file format of HTTP_LOGFILE_NONE and will disable logging by the server.

lpszFileName

A pointer to a string that specifies the name of the log file that should be created or appended to. If the server was configured with logging enabled and this parameter is NULL or an empty string, the current log file name will not be changed. If the log file does not exist, it will be created. If it does exist, the contents of the log file will be appended to.

Return Value

If the method succeeds, the return value is non-zero. If one of the parameters are invalid, the method will return zero.

Remarks

The **SetLogFile** method can be used to change the current log file name, the format of the log file or the level of detail recorded in the log file. In some situations it may be desirable to delete the current log file contents when changing the format or ensure that a new log file is created. To do this,

combine the *nLogFormat* parameter with the constant HTTP_LOGFILE_DELETE.

The higher the value of the *nLogLevel* parameter, the greater the level of detail that is recorded by the server. A log level of 1 instructs the server to only record GET, POST and PUT requests, while a level of 10 instructs the server to record all commands processed by the server. Because a higher level of logging detail can negatively impact the performance of the server, it is recommended that you do not exceed a level of 5 for most applications. A log level of 10 should only be used for debugging purposes.

Example

```
UINT nLogFormat = HTTP_LOGFILE_NONE;
UINT nLogLevel = 0;
UINT nNewLevel = 5;
BOOL bChanged = FALSE;

// Change the level of detail for the current log file if logging
// has been enabled and the current level is a lower value

if (pHttpServer->GetLogFile(&nLogFormat, &nLogLevel, NULL, 0))
{
    if (nLogFormat != HTTP_LOGFILE_NONE && nLogLevel < nNewLevel)
        bChanged = pHttpServer->SetLogFile(nLogFormat, nNewLevel, NULL);
}
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetLogFile](#), [RenameServerLogFile](#)

CHttpServer::SetName Method

```
BOOL SetName(  
    UINT nClientId,  
    LPCTSTR lpszHostName  
);
```

Change the host name assigned to the specified server or client session.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session. This value may be zero.

lpszHostName

A pointer to a string that specifies the new host name assigned to the server or client session. If this value is NULL or points to an empty string, the current host name will be changed to use the default host name.

Return Value

If the method succeeds, the return value is non-zero. If the client ID is invalid, or the buffer is not large enough to store the complete hostname, the method will return a value of zero.

Remarks

This method will change the host name assigned to the specified client session. If the *nClientId* parameter has a value of zero, the method will change default host name that was assigned to the server as part of the server configuration. If the *nClientId* parameter specifies a valid client session and the *lpszHostName* parameter is NULL, the host name associated with the client session will be changed to the current host name assigned to the server.

When a client connects to the server, it can specify the host name that it used to establish the connection by sending the HOST command. This is typically used with virtual hosting, where one server may accept client connections for multiple domains. The **GetName** method will return the host name specified by the client, and **SetName** can be used by the application to either explicitly assign a different host name to the client session, or override the host name provided by the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstdlib11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetAddress](#), [GetName](#)

CHttpServer::SetOptions Method

```
BOOL SetOptions(  
    DWORD dwOptions  
);
```

Sets the default options for this instance of the server.

Parameters

dwOptions

An unsigned integer which specifies one or more options. For a list of available options, see [Server Option Constants](#).

Return Value

If the method is successful, it will return a non-zero value, otherwise it will return a value of zero.

Remarks

The **SetOptions** method changes the default options for the current instance of the server. This method cannot be used to change the options for an active instance of the server. If the server is active, it must be stopped before calling this method. To get the current options, use the **GetOptions** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[GetOptions](#)

CHttpServer::SetPriority Method

```
INT SetPriority(  
    INT nPriority  
);
```

Change the priority assigned to the specified server.

Parameters

nPriority

An integer value which specifies the new priority for the server. It may be one of the following values:

Value	Description
HTTP_PRIORITY_BACKGROUND	This priority significantly reduces the memory, processor and network resource utilization for the server. It is typically used with lightweight services running in the background that are designed for few client connections. The server thread will be assigned a lower scheduling priority and will be frequently forced to yield execution to other threads.
HTTP_PRIORITY_LOW	This priority lowers the overall resource utilization for the server and meters the processor utilization for the server thread. The server thread will be assigned a lower scheduling priority and will occasionally be forced to yield execution to other threads.
HTTP_PRIORITY_NORMAL	The default priority which balances resource and processor utilization. This is the priority that is initially assigned to the server when it is started, and it is recommended that most applications use this priority.
HTTP_PRIORITY_HIGH	This priority increases the overall resource utilization for the server and the thread will be given higher scheduling priority. It is not recommended that this priority be used on a system with a single processor.
HTTP_PRIORITY_CRITICAL	This priority can significantly increase processor, memory and network utilization. The server thread will be given higher scheduling priority and will be more responsive to client connection requests. It is not recommended that this priority be used on a system with a single processor.

Return Value

If the method succeeds, the return value is the previous priority assigned to the server. If the method fails, the return value is HTTP_PRIORITY_INVALID. To get extended error information, call the **GetLastError** method.

Remarks

The **SetPriority** method can be used to change the current priority assigned to the specified server. Client connections that are accepted after this method is called will inherit the new priority as their

default priority. Previously existing client connections will not be affected by this method.

Higher priority values increase the thread priority and processor utilization for each client session. You should only change the server priority if you understand the impact it will have on the system and have thoroughly tested your application. Configuring the server to run with a higher priority can have a negative effect on the performance of other programs running on the system.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h.

Import Library: cshtsv11.lib

See Also

[GetPriority](#), [Start](#)

CHttpServer::SetStackSize Method

```
BOOL SetStackSize(  
    DWORD dwStackSize  
);
```

Change the initial size of the stack allocated for threads created by the server.

Parameters

dwStackSize

The amount of memory that will be committed to the stack for each thread created by the server. If this value is zero, a default stack size will be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **SetStackSize** method changes the initial amount of memory that is committed to the stack for each thread created by the server. By default, the stack size for each thread is set to 256K for 32-bit processes and 512K for 64-bit processes. Increasing or decreasing the stack size will only affect new threads that are created by the server, it will not affect those threads that have already been created to manage active client sessions. It is recommended that most applications use the default stack size.

You should not change the stack size unless you understand the impact that it will have on your system and have thoroughly tested your application. Increasing the initial commit size of the stack will remove pages from the total system commit limit, and every page of memory that is reserved for stack cannot be used for any other purpose.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[GetMemoryUsage](#), [GetStackSize](#), [Start](#)

CHttpServer::SetUuid Method

```
BOOL SetUuid(  
    LPCTSTR lpszHostUuid  
);
```

Assign a UUID to the current instance of the server.

Parameters

lpszHostUuid

A pointer to a string that specifies the server UUID, terminated with a null character. This value can be used when storing information about the server, and should be generated using a utility such as **uuidgen** which is included with Visual Studio. This parameter may be NULL or point to an empty string, in which case a temporary UUID will be randomly generated for the server.

Return Value

If the method succeeds, the return value is non-zero, otherwise the method return a value of zero.

Remarks

The **SetUuid** method assigns a Universally Unique Identifier (UUID) to the server. The UUID may either be generated by the application and assigned as part of the server configuration, or an ephemeral UUID may be automatically generated when the server is started. This method cannot be used to change the UUID after the server has been started. To determine the UUID assigned to an active server instance, use the **GetUuid** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetUuid](#)

CHttpServer::Start Method

```
BOOL Start(  
    LPCTSTR lpszLocalHost,  
    UINT nLocalPort,  
    DWORD dwOptions  
);  
  
BOOL Start(  
    LPCTSTR lpszLocalHost,  
    UINT nLocalPort  
);  
  
BOOL Start(  
    UINT nLocalPort  
);
```

The **Start** method begins listening for client connections on the specified local address and port number. The server is started in its own thread and manages the client sessions independently of the calling thread. All interaction with the server and its client sessions takes place inside the class event handlers.

Parameters

lpszLocalHost

A pointer to a string which specifies the local hostname or IP address address that the server should be bound to. If this parameter is omitted or specifies a NULL pointer an appropriate address will automatically be used. If a specific address is used, the server will only accept client connections on the network interface that is bound to that address.

nLocalPort

The port number the server should use to accept client connections. If a value of zero is specified, the server will use the standard port number 21 to listen for connections, or port 990 if the server is configured to use implicit TLS. The port number used by the application must be unique and multiple instances of a server cannot use the same port number. It is recommended that a port number greater than 5000 be used for private, application-specific implementations.

dwOptions

An unsigned integer value that specifies one or more options to be used when creating an instance of the server. For a list of the available options, see [Server Option Constants](#). If this parameter is omitted, the default options for the server instance will be used.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call the **GetLastError** method.

Remarks

In most cases, the *lpszLocalHost* parameter should be omitted or a NULL pointer. On a multihomed system, this will enable the server to accept connections on any appropriately configured network adapter. Specifying a hostname or IP address will limit client connections to that particular address. Note that the hostname or address must be one that is assigned to the local system, otherwise an error will occur.

If an IPv6 address is specified as the local address, the system must have an IPv6 stack installed and configured, otherwise the method will fail.

To listen for connections on any suitable IPv4 interface, specify the special dotted-quad address "0.0.0.0". You can accept connections from clients using either IPv4 or IPv6 on the same socket by specifying the special IPv6 address "::0", however this is only supported on Windows 7 and Windows Server 2008 R2 or later platforms. If no local address is specified, then the server will only listen for connections from clients using IPv4. This behavior is by design for backwards compatibility with systems that do not have an IPv6 TCP/IP stack installed.

The handle returned by this method references the listening socket that was created when the server was started. The service is managed in another thread, and all interaction with the server and active client connections are performed inside the event handlers. To disconnect all active connections, close the listening socket and terminate the server thread, call the **Stop** method.

The host UUID that is defined as part of the server configuration should be generated using the **uuidgen** utility that is included with the Windows SDK. You should not use the UUID that is provided in the example code, it is for demonstration purposes only. If no host UUID is specified in the server configuration, an ephemeral UUID will be generated automatically when the server is started.

Example

```
CHttpServer *pHttpServer = new CHttpServer();

// Initialize the server configuration
pHttpServer->SetName(_T("server.company.com"));
pHttpServer->SetUuid(_T("10000000-1000-1000-1000-100000000000"));
pHttpServer->SetDirectory(_T("%ProgramData%\\MyProgram\\Server"));
pHttpServer->SetLogFile(HTTP_LOGFILE_EXTENDED, 5,
    _T("%ProgramData%\\MyProgram\\Server.log"));
pHttpServer->SetOptions(HTTP_SERVER_DEFAULT);

// Start the server
pHttpServer->Start(HTTP_PORT_DEFAULT);
```

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[EnumClients](#), [Restart](#), [Stop](#)

CHttpServer::Stop Method

BOOL Stop();

Stop the server, terminating all active client sessions and releasing the resources that were allocated for the server.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero.

Remarks

The **Stop** method instructs the server to stop accepting client connections, disconnects all active client connections and terminates the thread that is managing the server session. The handle is no longer valid after the server has been stopped and should no longer be used. Note that it is possible that the actual handle value may be re-used at a later point when a new server is started. An application should always consider the server handle to be opaque and never depend on it being a specific value.

If an application calls this method from within an event handler, the active client session (the client for which the event handler was invoked) may not get a disconnect notification. It is recommended that this method only be called by the same thread that created the server using the **Start** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[Restart](#), [Start](#)

CHttpServer::Suspend Method

BOOL Suspend();

Suspend the server and reject new client connections.

Parameters

None.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Suspend** method instructs the server to suspend accepting new client connections. Any incoming client connections will be rejected with an error message indicating that the server is currently unavailable. To resume accepting client connections, call the **Resume** method. Suspending the server will have no effect on clients that have already established a connection with the server.

It is recommended that you only suspend a server if absolutely necessary, and only for brief periods of time. If you want to limit the number of active client connections or control the connection rate for clients, use the **Throttle** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

See Also

[Restart](#), [Resume](#), [Start](#), [Stop](#), [Throttle](#)

CHttpServer::Throttle Method

```
BOOL Throttle(  
    UINT nMaxClients,  
    UINT nMaxClientsPerAddress,  
    DWORD dwConnectionRate  
);
```

The **Throttle** method limits the number of active client connections, connections per address and connection rate.

Parameters

nMaxClients

A value which specifies the maximum number of clients that may connect to the server. A value of zero specifies that there is no fixed limit to the number of client connections.

nMaxClientsPerAddress

A value which specifies the maximum number of clients that may connect to the server from the same IP address. A value of zero specifies that there is no fixed limit to the number of client connections per address. By default, there is a limit of four client connections per address.

dwConnectionRate

A value which specifies a restriction on the rate of client connections, limiting the number of connections that will be accepted within that period of time. A value of zero specifies that there is no restriction on the rate of client connections. The higher this value, the fewer the number of connections that will be accepted within a specific period of time. By default, there is no limit on the client connection rate.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **Throttle** method is used to limit the number of connections and the connection rate to minimize the potential impact of a large number of client connections over a short period of time. This can be used to protect the server from a client application that is malfunctioning or a deliberate denial-of-service attack in which the attacker attempts to flood the server with connection attempts.

If the maximum number of client connections or maximum number of connections per address is exceeded, the server will reject subsequent connection attempts until the number of active client sessions drops below the specified threshold. Note that adjusting these values lower than the current connection limits will not affect clients that have already connected to the server. For example, if the **Start** method is called with the maximum number of clients set to 100, and then **Throttle** is called lowering that value to 75, no existing client connections will be affected by the change. However, the server will not accept any new connections until the number of active clients drops below 75.

Increasing the connection rate value will force the server to slow down the rate at which it will accept incoming client connection requests. For example, setting this parameter to a value of 1000 would limit the server to accepting one client connection every second, while a value of 250 would allow the server to accept four client connections per second. Note that significantly increasing the amount of time the server must wait to accept client connections can exceed the connection backlog queue, resulting in client connections being rejected.

It is recommended that you always specify conservative connection limits for your server application based on expected usage. Allowing an unlimited number of client connections can potentially expose the system to denial-of-service attacks and should never be done for servers that are accessible over the Internet.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

CHttpServer Event Handlers

Method	Description
OnAuthenticate	The client requested authentication
OnConnect	The client established a control connection to the server
OnCommand	The client issued a command to the server
OnDisconnect	The client has disconnected from the server
OnDownload	The client has downloaded a file from the server
OnError	The event handler encountered an error when processing a client event
OnExecute	The client has executed an external program on the server
OnResult	The command issued by the client has been processed by the server
OnTimeout	The client has exceeded the maximum allowed idle time
OnUpload	The client has uploaded a file to the server

CHttpServer::OnAuthenticate Method

```
virtual void OnAuthenticate(  
    UINT nClientId,  
    LPCTSTR lpszHostName,  
    LPCTSTR lpszUserName,  
    LPCTSTR lpszPassword  
);
```

A virtual method that is invoked after the client has successfully downloaded a file from the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszHostName

A pointer to a string that specifies the host name that the client used to establish the connection.

lpszUserName

A pointer to a string that specifies the user name provided by the client.

lpszPassword

A pointer to a string that specifies the cleartext user password provided by the client.

Return Value

None.

Remarks

The **OnAuthenticate** event handler is invoked when the client has provided authentication credentials as part of the request for a document or other resource. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

The event handler can call the **AuthenticateClient** method to authenticate the client session. If the event handler does not authenticate the client, the server will perform its default authentication. To reject the credentials provided by the client, use the **SendErrorResponse** method with a result code of 401.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[OnCommand](#), [OnConnect](#)

CHttpServer::OnCommand Method

```
virtual void OnCommand(  
    UINT nClientId,  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszResource,  
    LPCTSTR lpszParameters,  
    BOOL& bHandled  
);
```

A virtual method that is invoked after the client has sent a command to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string that specifies the command issued by the client. The command name will always be capitalized. For a complete list of commands supported by the server, see [Server Commands](#).

lpszResource

A pointer to a string that specifies the resource that the client has requested. Depending on the command issued, it may be a document, a folder or an executable script.

lpszParameters

A pointer to a string that specifies any query parameters that have been provided by the client. The string will be empty if there were no query parameters included with the request. The query parameters in this string will be URL encoded.

bHandled

An integer value that indicates whether the handler has processed the event. If the handler sets this parameter to a non-zero value, it indicates that the application has processed the command itself. If this parameter has a value of zero, then the server will perform the default action for the command. By default, this parameter has a value of zero.

Return Value

None.

Remarks

The **OnCommand** event handler is invoked after the client has sent a command to the server, but before the command has been processed. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

This event handler is invoked for all commands issued by the client, including invalid or disabled commands. If the **bHandled** parameter is FALSE, the server will perform the default processing for the command. If the **bHandled** parameter is set to TRUE, the server will take no action. Note that if the event handler processes the command, it must call the **SendResponse** method to send a success or error response back to the client. If this is not done, the server will consider the command to be invalid and will send a 501 "not implemented" error by default.

It is not necessary to use this event handler to disable a command. The **EnableCommand** method can be used to enable or disable specific commands, and the **IsCommandEnabled** method can be used to determine if a command is enabled.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisconnectClient](#), [EnableCommand](#), [IsCommandEnabled](#), [OnDisconnect](#), [SendResponse](#)

CHttpServer::OnConnect Method

```
virtual void OnConnect(  
    UINT nClientId,  
    LPCTSTR lpszAddress  
);
```

A virtual method that is invoked after the client has connected to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszAddress

A pointer to a string that specifies the IP address of the client. This address may either be in IPv4 or IPv6 format, depending on how the server was configured and the address the client used to establish the connection.

Return Value

None.

Remarks

The **OnConnect** event handler is invoked after the client has connected to the server. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

This event only occurs after the server has checked the active client limits and has accepted the connection. If the server was started with security enabled, the TLS handshake has been performed. If the server has been suspended, or the limit on the maximum number of client sessions has been exceeded, the server will terminate the client session prior to this event handler being invoked.

If this event handler is not implemented, the server will perform the default action of accepting the connection and waiting for the client to send a request for a document. To reject a connection, call the **DisconnectClient** method to terminate the client session.

Your server application should never make the assumption that for each **OnConnect** event there will be one command issued by the client. A client may issue multiple commands per session, and in some cases a client may send no commands to the server. If the client is using HTTP 1.0, connections will not be persistent. This means that the client will connect to the server, issue one command and then disconnect. For clients that use HTTP 1.1, multiple commands may be issued using a single connection. There is no guarantee that either the client or server will maintain a persistent connection, and either may request that the connection be closed after a command has completed.

If the client is a web browser, it is not unusual to see multiple, simultaneous connections being established with your server for a single request. Do not be concerned if you see multiple connections without any commands being issued. Browsers will do this to in anticipation of downloading additional assets (stylesheets, images, etc.) to improve performance and will typically close any unused connections after a few seconds. You may also see multiple requests for the file **/favicon.ico**. The browser will request this icon to display in the browser address bar and bookmarks. If the file does not exist, the browser ignores the error response from the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DisconnectClient](#), [OnCommand](#), [OnDisconnect](#),

CHttpServer::OnDisconnect Method

```
virtual void OnDisconnect(  
    UINT nClientId  
);
```

A virtual method that is invoked immediately before the client is disconnected from the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

Return Value

None.

Remarks

The **OnDisconnect** event handler is invoked immediately before the client is disconnected from the server. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

This is an advisory event and it is not required for the application to explicitly disconnect the client or perform any action. The event handler cannot prevent the client from disconnecting. Applications that implement a handler for this event should only use it to update any private data that was associated with the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

[OnConnect](#)

CHttpServer::OnDownload Method

```
virtual void OnDownload(  
    UINT nClientId,  
    LPCTSTR lpszFileName,  
    DWORD dwTimeElapsed,  
    ULARGE_INTEGER uiBytesCopied  
);
```

A virtual method that is invoked after the client has successfully downloaded a file from the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the local path name of the file that was downloaded from the server. The path will always include the disk volume or share name, and the path delimiter will always be the backslash character.

dwTimeElapsed

An unsigned integer value that specifies the number of milliseconds that it took to complete the file transfer.

uiBytesCopied

An unsigned 64-bit integer value that specifies the number of bytes of data that was downloaded by the client.

Return Value

None.

Remarks

The **OnDownload** event handler is invoked after the client has successfully downloaded a file from the server using the GET command. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

The ULARGE_INTEGER structure is actually a union that is used to represent a 64-bit value. If the compiler has built-in support for 64-bit integers, use the **QuadPart** member to access the 64-bit integer value. Otherwise, use the **LowPart** and **HighPart** members to access the value.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[OnCommand](#), [OnUpload](#)

CHttpServer::OnError Method

```
virtual void OnConnect(  
    UINT nClientId,  
    UINT nEventId,  
    DWORD dwError  
);
```

A virtual method that is invoked when the event handler encountered an error when processing a client event.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nEventId

An unsigned integer which identifies the client event that was being processed when the error occurred. For a list of event identifiers, see [Server Event Constants](#).

dwError

An unsigned integer value that specifies the error code.

Return Value

None.

Remarks

The **OnError** event handler is invoked whenever an error occurs while an event is being processed by the server. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

It is important to note that this event is not raised for every error that occurs. The event only occurs when another event is being processed and an unhandled error occurs that must be reported back to the server application. The following are some common situations in which this event handler may be invoked:

- A network error occurs when the client connection is being accepted by the server. This could be the result of an aborted connection or some other lower-level failure reported by the networking subsystem on the server.
- The server is configured to use implicit TLS but cannot obtain the security credentials required to create the security context for the session. Usually this indicates that the server certificate cannot be found, or the certificate does not have a private key associated with it. It could also indicate a general problem with the cryptographic subsystem where the client and server could not successfully negotiate a cipher suite.
- A network error occurs when attempting to process a command issued by the client. This usually indicates that the connection to the client has been aborted, either because the client is not acknowledging the data that has been exchanged with the server, or the client has terminated abnormally. This event will not occur if the client terminates the connection normally.

In most situations where this event handler is invoked, the error is not recoverable and the only action that can be taken is to terminate the client session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

See Also

[GetLastError](#), [OnConnect](#), [OnCommand](#)

CHttpServer::OnExecute Method

```
virtual void OnExecute(  
    UINT nClientId,  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszResource,  
    LPCTSTR lpszParameters,  
    DWORD dwExitCode  
);
```

A virtual method that is invoked after the client has successfully executed a CGI program or script on the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string that specifies the command issued by the client. The command name will always be capitalized. For a complete list of commands supported by the server, see [Server Commands](#).

lpszResource

A pointer to a string that specifies the resource that the client has requested.

lpszParameters

A pointer to a string that specifies any query parameters that have been provided by the client. The string will be empty if there were no query parameters included with the request. The query parameters in this string will be URL encoded.

dwExitCode

An unsigned integer that specifies the exit code that was returned by the program.

Return Value

None.

Remarks

The **OnExecute** event handler is invoked after the client has successfully executed an external CGI program or script. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

External programs must be registered by the server application using the **RegisterProgram** method. To enable the use of scripts, the **RegisterHandler** method can be used to associate an executable program with a specific file extension.

The **GetProgramOutput** method can be used to obtain the unfiltered output from the external command, while the **GetProgramText** method will return filtered output from the program that contains only printable text characters.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::OnResult Method

```
virtual void OnResult(  
    UINT nClientId,  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszResource,  
    LPCTSTR lpszParameters,  
    UINT nResultCode  
);
```

A virtual method that is invoked after the server has processed a command issued by the client.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszCommand

A pointer to a string that specifies the command issued by the client. The command name will always be capitalized. For a complete list of commands supported by the server, see [Server Commands](#).

lpszResource

A pointer to a string that specifies the resource that the client has requested. Depending on the command issued, it may be a document, a folder or an executable script.

lpszParameters

A pointer to a string that specifies any query parameters that have been provided by the client. The string will be empty if there were no query parameters included with the request. The query parameters in this string will be URL encoded.

nResultCode

A integer value that specifies the result code that was sent to the client.

Return Value

None.

Remarks

The **OnResult** event handler is invoked after the server has processed a command issued by the client. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstoools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer::OnTimeout Method

```
virtual void OnTimeout(  
    UINT nClientId,  
    UINT nIdleTime,  
    UINT nElapsed  
);
```

A virtual method that is invoked after the client has exceeded the maximum allowed idle time.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

nIdleTime

An unsigned integer value that specifies the current idle timeout period for the client in seconds.

nElapsed

An unsigned integer value that specifies the number of seconds that the client has been idle.

Return Value

None.

Remarks

The **OnTimeout** event handler is invoked after the client has exceeded the maximum allowed idle time. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

This event handler will be invoked prior to the client being disconnected from the server. This event will never occur while the server is returning data to the client. The **SetClientIdleTime** method can be used to change or refresh the idle timeout period for the session.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: cshtsv11.lib

CHttpServer::OnUpload Method

```
virtual void OnUpload(  
    UINT nClientId,  
    LPCTSTR lpszFileName,  
    DWORD dwTimeElapsed,  
    ULARGE_INTEGER uiBytesCopied  
);
```

A virtual method that is invoked after the client has successfully uploaded a file to the server.

Parameters

nClientId

An unsigned integer which uniquely identifies the client session.

lpszFileName

A pointer to a string that specifies the local path name of the file that was uploaded to the server. The path will always include the disk volume or share name, and the path delimiter will always be the backslash character.

dwTimeElapsed

An unsigned integer value that specifies the number of milliseconds that it took to complete the file transfer.

uiBytesCopied

An unsigned 64-bit integer value that specifies the number of bytes of data that was uploaded by the client.

Return Value

None.

Remarks

The **OnUpload** event handler is invoked after the client has successfully uploaded a file to the server using the PUT command. To implement an event handler, the application should create a class derived from the **CHttpServer** class, and then override this method.

The ULARGE_INTEGER structure is actually a union that is used to represent a 64-bit value. If the compiler has built-in support for 64-bit integers, use the **QuadPart** member to access the 64-bit integer value. Otherwise, use the **LowPart** and **HighPart** members to access the value.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: cshtsv11.lib

Unicode: Implemented as Unicode and ANSI versions

CHttpServer Data Structures

- [HTTPCLIENTCREDENTIALS](#)
- [HTTPREQUEST](#)
- [HTTPRESPONSE](#)
- [HTTPSERVERTRANSFER](#)

HTTPCLIENTCREDENTIALS

The **HTTPCLIENTCREDENTIALS** structure defines the credentials used to authenticate a specific user.

```
typedef struct _HTTPCLIENTCREDENTIALS
{
    DWORD dwSize;
    DWORD dwFlags;
    UINT  nAuthType;
    UINT  nHostPort;
    TCHAR szHostName[HTTP_MAXHOSTNAME];
    TCHAR szUserName[HTTP_MAXUSERNAME];
    TCHAR szPassword[HTTP_MAXPASSWORD];
} HTTPCLIENTCREDENTIALS, *LPHTTPCLIENTCREDENTIALS;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwFlags

An unsigned integer value is reserved for future use. This value will always be zero.

nAuthType

An unsigned integer value that identifies the authentication method.

nHostPort

The server port number.

szHostName

A pointer to a string that specifies the server host name.

szUserName

A pointer to a string that specifies the user name.

szPassword

A pointer to a string that specifies the user password.

Remarks

When an instance of this structure is passed to the **GetClientCredentials** method, this member must be initialized to the size of the structure and all other members must be initialized with a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetClientCredentials](#)

HTTPREQUEST

The **HTTPREQUEST** structure provides information about the request made by the client.

```
typedef struct _HTTPREQUEST
{
    DWORD    dwSize;
    DWORD    dwFlags;
    DWORD    dwVersion;
    DWORD    dwAccess;
    DWORD    dwLength;
    DWORD    dwReserved;
    UINT     nHostId;
    UINT     nHostPort;
    LPCSTR   lpszCommand;
    LPCSTR   lpszHostName;
    LPCSTR   lpszUserName;
    LPCSTR   lpszPassword;
    LPCSTR   lpszResource;
    LPCSTR   lpszParameters;
    LPCSTR   lpszDirectory;
    LPCSTR   lpszPathInfo;
    LPCSTR   lpszProgram;
    LPCSTR   lpszScriptFile;
    LPCSTR   lpszLocalFile;
    LPCSTR   lpszMediaType;
} HTTPREQUEST, *LPHTTPREQUEST;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwFlags

An unsigned integer value that provides additional information about the request. It may be one or more of the following values:

Value	Description
HTTP_REQUEST_FLAG_PROTECTED	The resource that the client has requested is protected. The client should only be permitted to access the resource if the client session has been authenticated.
HTTP_REQUEST_FLAG_PROGRAM	The resource that the client has requested is a CGI program or an executable script. The output from the program or script should be returned to the client in the response. If this flag is specified, the <i>lpszProgram</i> member of the structure specifies the name of the program that should be executed.
HTTP_REQUEST_FLAG_SCRIPT	The resource that the client has requested is an executable script. This flag is set when the request URL is mapped to a registered script handler. The <i>lpszProgram</i> member specifies the name of the program that is responsible for executing the script, and the <i>lpszScriptFile</i> parameter specifies the full

path to the script itself.

dwVersion

An unsigned integer value that specifies the protocol version used. It may be one of the following values:

Value	Description
HTTP_VERSION_09	The client issued a GET command without specifying a protocol version.
HTTP_VERSION_10	The client issued a command that specified version 1.0 of the protocol.
HTTP_VERSION_11	The client issued a command that specified version 1.1 of the protocol.

dwAccess

An unsigned integer value that specifies the access permissions that were assigned to the resource. For a list of file access permissions, see [User and File Access Constants](#).

dwLength

An unsigned integer value that will specify the number of bytes of request data provided by the client. If the client did not submit any data with the request, this member will have a value of zero.

dwReserved

An unsigned integer value that is reserved for future use.

nHostId

An integer value that identifies the virtual host that was specified by the client. This is based on the value of the Host request header included in the request. This value will be zero if a host name is not specified by the client, or does not match one of the virtual hosts that have been created.

nHostPort

An integer value that specifies the port number that the client used to establish the connection. This will be the same port number that was used when starting the server.

lpszCommand

A pointer to a string that specifies the command that was issued by the client. The command will always be in upper case. Refer to [Hypertext Transfer Protocol Commands](#) for a list of standard commands.

lpszHostName

A pointer to a string that identifies the hostname or IP address that the client used to establish the connection. This will typically correspond to the hostname assigned to the server, or to one of the virtual hosts that have been created.

lpszUserName

A pointer to a string that specifies the username provided with the request. This member is only set if the client has included authentication credentials as part of the request. If the client has not provided any credentials, this member will be NULL.

lpszPassword

A pointer to a string that specifies the password provided with the request. This member is only set if the client has included authentication credentials as part of the request. If the client has not provided any credentials, this member will be NULL.

lpzResource

A pointer to a string that specifies the URL path provided by the client.

lpzParameters

A pointer to a string that specifies any query parameters that were included in the request made by the client. If the URL did not include any query parameters, this member will be NULL.

lpzDirectory

A pointer to a string the specifies the full path to the root directory for the virtual host.

lpzPathInfo

A pointer to a string that specifies additional path information provided by the client when referencing an executable CGI program or script in the URL. For example, if a program is mapped to the virtual path "/orders/invoice" and the client requests "/orders/invoice/pdf/10001" this member will be the string "/pdf/10001". If there is no path information associated with the request, this member will be NULL.

lpzProgram

A pointer to a string that specifies the local path to the CGI program that should be executed to process the request made by the client. If this member is NULL, it indicates that the client has provided a URL that maps to a local file or directory.

lpzScriptFile

A pointer to a string that specifies the local path to the script file that will be executed by the handler. If this member is NULL, it indicates that the request URL was not mapped to registered script handler.

lpzLocalFile

A pointer to a string that specifies the local path to the directory or file name referenced by the URL. If the *lpzPathInfo* member is not NULL, then this member will point to a local file name based the path information appended to the root directory for the virtual host.

lpzMediaType

A pointer to a string that identifies the request data using the standard Internet media types defined in RFC 2046. It is used to designate the format for various types of content and has two parts, a primary and secondary media type separated by a forward slash. Common examples are "text/plain", "text/html" and "application/octet-stream". If the client did not submit any data with the request, this member will be NULL.

Remarks

This structure is used with the **ReceiveRequest** method and all members should be initialized to a value of zero, except for the *dwSize* member which should be initialized to size of the structure. Failure to properly initialize the structure will cause the method call to fail.

The value of the *lpzLocalFile* member depends on whether the client has requested a static document, or if the URL is mapped to a registered program or script handler. If the request is for a static document, then the *dwFlags* member will not have the HTTP_REQUEST_FLAG_PROGRAM bit flag set and the *lpzLocalFile* member will be the full path to the document. If the URL is mapped to a registered program or script, then the *lpzLocalFile* member will be the full path to the server root directory, If the request URL included additional path information, that will be appended to the root directory.

The value of the *lpzScriptFile* member is only defined if the *dwFlags* member has the HTTP_REQUEST_FLAG_SCRIPT bit flag set. This indicates that the request URL references a file that is an executable script with a handler that was registered using the **RegisterHandler** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

See Also

[ReceiveRequest](#), [SendResponse](#), [HTTPRESPONSE](#)

HTTPRESPONSE

The **HTTPRESPONSE** structure provides additional information about the response to the client.

```
typedef struct _HTTPRESPONSE
{
    DWORD    dwSize;
    DWORD    dwFlags;
    DWORD    dwVersion;
    DWORD    dwReserved;
    UINT     nExpires;
    UINT     nResultCode;
    LPCTSTR  lpszReason;
    LPCTSTR  lpszMediaType;
} HTTPRESPONSE, *LPHTTPRESPONSE;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwFlags

An unsigned integer value that specifies one or more response flags. This member is reserved for future use and should always have a value of zero.

dwVersion

An unsigned integer value that specifies the protocol version used. It may be one of the following values:

Value	Description
HTTP_VERSION_DEFAULT	The server should respond to the client using the same version specified in the request.
HTTP_VERISON_10	The server should respond to the client using version 1.0 of the protocol.
HTTP_VERSION_11	The server should respond to the client using version 1.1 of the protocol.

dwReserved

An unsigned integer value that is reserved for future use.

nExpires

An integer value that specifies the number of seconds until the client should consider any cached response data to be stale. If this value is zero, the default cache expiration time for the server will be used. The default cache expiration time is 7200 seconds (2 hours). The value of this structure member is ignored if the HTTP_RESPONSE_NOCACHE option is specified when the response is sent to the client.

nResultCode

An integer value that specifies the result code that should be sent in response to the client request. The result code is a three-digit number that indicates success or failure. For more information, refer to the **GetCommandResult** method.

lpszReason

A string that describes the result code sent to the client. The description should be brief and

should not contain any formatting characters or HTML markup. This parameter may be NULL, in which case a default description of the result code will be used.

lpzMediaType

A string that specifies the Internet media type for the data that is being sent to the client as defined in RFC 2046. The format for the content type string consists of two parts, a primary and secondary media type separated by a forward slash. Common examples are "text/plain", "text/html" and "application/octet-stream". If this member is NULL, the library will attempt to automatically determine the appropriate media type.

Remarks

This structure is used with the **SendResponse** method and the *dwSize* member must be initialized to size of the structure. Failure to properly initialize the structure will cause the method call to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

[GetCommandResult](#), [ReceiveRequest](#), [SendResponse](#), [HTTPREQUEST](#)

HTTPSERVERTRANSFER

The **HTTPSERVERTRANSFER** structure provides information about the last file transfer performed by a client.

```
typedef struct _HTTPSERVERTRANSFER
{
    DWORD          dwSize;
    DWORD          dwReserved;
    DWORD          dwFileAccess;
    DWORD          dwTimeElapsed;
    ULARGE_INTEGER uiBytesCopied;
    TCHAR          szFileName[MAX_PATH];
} HTTPSERVERTRANSFER, *LPHTTPSERVERTRANSFER;
```

Members

dwSize

An unsigned integer value that specifies the size of the structure.

dwReserved

An unsigned integer value that is reserved for future use. This value will always be zero.

dwFileAccess

An unsigned integer value that specifies the how the local file was accessed. It can be one of the following values:

Value	Description
HTTP_FILE_READ	The file was opened for reading. This mode indicates that the client issued the GET command to download the contents of a file from the server to the client system. The <i>szFileName</i> member specifies the name of the local file on the server that was downloaded by the client.
HTTP_FILE_WRITE	The file was opened for writing. This mode indicates that the client issued the PUT command to upload the contents of a file from the client system to server. The <i>szFileName</i> member specifies the name of the local file on the server that was created by the client. If a file already existed with the name name, it was replaced.

dwTimeElapsed

The amount of time that it took for the file transfer to complete in milliseconds. This value is limited to the resolution of the system timer, which is typically in the range of 10 to 16 milliseconds. This value may be zero if the transfer occurred over a local network or on the same host using a loopback address.

uiBytesCopied

A 64-bit integer value that specifies the total number of bytes copied during the file transfer. This value is represented by a ULARGE_INTEGER union which provides support for those programming languages that do not have intrinsic support for 64-bit integers. For more information, refer to the Windows SDK documentation. The application should not make the assumption that this is the actual size of the file.

szFileName

A pointer to a string value that will contain the full path to the local file that was transferred. The *dwFileAccess* member determines whether the file name represents a file that was downloaded by

the client, or uploaded from the client and stored on the server.

Remarks

When an instance of this structure is passed to the **GetTransferInfo** method, the *dwSize* member must be initialized to the size of the structure, otherwise the method will fail with an error indicating that the parameter is invalid. All other members should be initialized to a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Unicode: Implemented as Unicode and ANSI versions

[GetTransferInfo](#)

SECURITYCREDENTIALS

The **SECURITYCREDENTIALS** structure specifies the information needed by the library to specify the security protocol and server certificate when accepting a secure connection.

```
typedef struct _SECURITYCREDENTIALS
{
    DWORD    dwSize;
    DWORD    dwProtocol;
    DWORD    dwOptions;
    DWORD    dwReserved;
    LPCTSTR  lpszHostName;
    LPCTSTR  lpszUserName;
    LPCTSTR  lpszPassword;
    LPCTSTR  lpszCertStore;
    LPCTSTR  lpszCertName;
    LPCTSTR  lpszKeyFile;
} SECURITYCREDENTIALS, *LPSECURITYCREDENTIALS;
```

Members

- dwSize*
Size of this structure. If the structure is being allocated dynamically, this member must be set to the size of the structure and all other unused structure members must be initialized to a value of zero or NULL.
- dwProtocol*
A bitmask of supported security protocols. The value of this structure member is constructed by using a bitwise operator with any of the following values:

Value	Description
SECURITY_PROTOCOL_DEFAULT	The default security protocol will be used when establishing a connection. This option will always request the latest version of the preferred security protocol and is the recommended value. Currently the default security protocol is TLS 1.2.
SECURITY_PROTOCOL_TLS	Either the TLS 1.2 or 1.3 protocol should be used when establishing a secure connection. The correct protocol is automatically selected, based on what version of the protocol is supported by the server. If this is the only protocol specified, SSL will be excluded from the list of supported protocols. This may be necessary for some servers which reject any attempt to use the older SSL protocol and require that only TLS be used.
SECURITY_PROTOCOL_TLS10	The TLS 1.0 protocol should be used when establishing a secure connection. This version is supported on all Windows platforms, however some servers may reject connections using version 1.0 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS11	The TLS 1.1 protocol should be used when establishing

	a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. Some servers may reject connections using version 1.1 in favor of using version 1.2. This version should only be used for backwards compatibility with older servers that have not been updated to use the current version of TLS.
SECURITY_PROTOCOL_TLS12	The TLS 1.2 protocol should be used when establishing a secure connection. This version is supported on Windows 7 and later desktop platforms, and Windows Server 2008 R2 and later server platforms. This version of TLS offers the broadest compatibility with most servers.
SECURITY_PROTOCOL_TLS13	The TLS 1.3 protocol should be used when establishing a secure connection. This is the newest version of the protocol and is only supported on Windows 11, Windows Server 2022 and later versions of Windows. If this version is not supported by the operating system, TLS 1.2 will be used instead.

dwOptions

A value which specifies one or options. This member is constructed by using a bitwise operator with any of the following values:

Value	Description
CREDENTIAL_STORE_CURRENT_USER	The library will attempt to open a store for the current user using the certificate store name provided in this structure. If no options are specified, then this is the default behavior.
CREDENTIAL_STORE_LOCAL_MACHINE	The library will attempt to open a local machine store using the certificate store name provided in this structure. If this option is specified, the library will always search for a local machine store before searching for the store by that name for the current user.
CREDENTIAL_STORE_FILENAME	The certificate store name is a file that contains the certificate and private key that will be used.

dwReserved

This structure member is reserved for future use and should always be initialized to zero.

lpszHostName

A pointer to a null terminated string which specifies the hostname that will be used when validating the server certificate. If this member is NULL, then the server certificate will be validated against the hostname used to establish the connection.

lpszUserName

A pointer to a null terminated string which identifies the owner of client certificate. Currently this member is not used by the library and should always be initialized as a NULL pointer.

lpszPassword

A pointer to a null terminated string which specifies the password needed to access the certificate. Currently this member is only used if the CREDENTIAL_STORE_FILENAME option has been specified. If there is no password associated with the certificate, then this member should be initialized as a NULL pointer.

lpszCertStore

A pointer to a null terminated string which specifies the name of the certificate store to open. A certificate store is a collection of certificates and their private keys, typically organized by how they are used. If this value is NULL or points to an empty string, the default certificate store "MY" will be used.

Store Name	Description
CA	Certification authority certificates. These are certificates that are issued by entities which are entrusted to issue certificates to other individuals or organizations. Companies such as Comodo and DigiCert act as certification authorities.
MY	Personal certificates and their associated private keys for the current user. This store typically holds the client certificates used to establish a user's credentials. This corresponds to the "Personal" store that is displayed by the certificate manager utility and is the default store used by the library.
ROOT	Certificates that have been self-signed by a certificate authority. Root certificates for a number of different certification authorities such as Comodo and DigiCert are installed as part of the operating system and periodically updated by Microsoft.

lpszCertName

A pointer to a null terminated string which specifies the name of the certificate to use. The library will first search the certificate store for a certificate with a matching "friendly name"; this is a name for the certificate that is assigned by the user. Note that the name must match completely, but the comparison is not case sensitive. If no matching certificate is found, the library will then attempt to find a certificate that has a matching common name (also called the certificate subject). This comparison is less stringent, and the first partial match will be returned. If this second search fails, the library will return an error indicating that the certificate could not be found. If the SECURITY_PROTOCOL_SSH protocol has been specified, this member should be NULL.

lpszKeyFile

This member is not used and should always be NULL. The private key cannot be specified separately and must be associated with the certificate.

Remarks

A client application only needs to create this structure if the server requires that the client provide a certificate as part of the process of negotiating the secure session. If a certificate is required, note that it must have a private key associated with it. Attempting to use a certificate that does not have a private key will result in an error during the connection process indicating that the client credentials could not be established.

If you are using a local certificate store, with the certificate and private key stored in the registry, you can explicitly specify whether the certificate store for the current user or the local machine (all users) should be used. This is done by prefixing the certificate store name with "HKCU:" for the current user,

or "HKLM:" for the local machine. For example, a certificate store name of "HKLM:MY" would specify the personal certificate store for the local machine, rather than the current user. If neither prefix is specified, then it will default to the certificate store for the current user. You can manage these certificates using the CertMgr.msc Microsoft Management Console (MMC) snap-in.

It is possible to load the certificate from a file rather than from current user's certificate store. The *dwOptions* member should be set to CREDENTIAL_STORE_FILENAME and the *lpCertStore* member should specify the name of the file that contains the certificate and its private key. The file must be in Private Information Exchange (PFX) format, also known as PKCS #12. These certificate files typically have an extension of .pfx or .p12. Note that if a password was specified when the certificate file was created, it must be provided in the *lpPassword* member or the library will be unable to access the certificate.

Note that the *lpUserName* and *lpPassword* members are values which are used to access the certificate store or private key file. They are not the credentials which are used when establishing the connection with the remote host or authenticating the client session.

Internet Control Message Protocol Class Library

Determine if a remote host is reachable and how packets of data are routed to that system.

Reference

- [Class Methods](#)
- [Data Structures](#)
- [Error Codes](#)

Library Information

Class Name	CIcmpClient
File Name	CSICMV11.DLL
Version	11.0.2218.1855
LibID	861142C8-68FD-4BC5-BAA9-25B33F15DD07
Import Library	CSICMV11.LIB
Dependencies	None
Standards	RFC 792

Overview

The Internet Control Message Protocol (ICMP) is commonly used to determine if a remote host is reachable and how packets of data are routed to that system. Users are most familiar with this protocol as it is implemented in the ping and traceroute command line utilities. The ping command is used to check if a system is reachable and the amount of time that it takes for a packet of data to make a round trip from the local system, to the remote host and then back again. The traceroute command is used to trace the route that a packet of data takes from the local system to the remote host, and can be used to identify potential problems with overall throughput and latency. The library can be used to build in this type of functionality in your own applications, giving you the ability to send and receive ICMP echo datagrams in order to perform your own analysis.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the

system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

Internet Control Message Protocol Class Methods

Class	Description
CicmpClient	Constructor which initializes the current instance of the class
~CicmpClient	Destructor which releases resources allocated by the class
Method	Description
AttachHandle	Attach the specified client handle to this instance of the class
AttachThread	Attach the specified client handle to another thread
Cancel	Cancel the current blocking operation
DetachHandle	Detach the handle for the current instance of this class
DisableEvents	Disable asynchronous event notification
DisableTrace	Disable logging of socket-level calls to the trace log
Echo	Send one or more echo datagrams to the specified host
EnableEvents	Enable asynchronous event notification
EnableTrace	Enable logging of network function calls to a file
FormatAddress	Convert a numeric IP address to a string
FreezeEvents	Suspend or resume event handling by the calling process
GetErrorString	Return a description for the specified error code
GetFirstHost	Return the first host from the traceroute
GetHandle	Return the client handle used by this instance of the class
GetHostAddress	Return the current host IP address
GetHostName	Return the current host name
GetLastError	Return the last error code
GetNextHost	Return the next host from the traceroute
GetPacketSize	Return the ICMP datagram packet size
GetRecvCount	Return the number of packets received
GetSendCount	Return the number of packets sent
GetSequenceId	Return the current sequence identifier
GetTimeout	Return the number of milliseconds until an operation times out
GetTimeToLive	Return the current time-to-live for the ICMP datagram
GetTripTime	Return the current trip time statistics
IcmpEventProc	Callback method that processes events generated by the client
IsBlocking	Determine if the client is blocked, waiting for information
IsInitialized	Determine if the class has been successfully initialized

RecvEcho	Read an ICMP datagram returned by the remote host
RegisterEvent	Register an event callback function
Reset	Reset the current client state
ResolveAddress	Resolve an IP address into a fully qualified host name
SendEcho	Send an ICMP datagram to the specified host
SetHostAddress	Set the IP address of the host to receive the next datagram
SetHostName	Set the name of the host to receive the next datagram
SetLastError	Set the last error code
SetPacketSize	Set the ICMP datagram packet size
SetSequenceId	Set the sequence identifier for the next datagram
SetTimeout	Set the number of milliseconds until an operation times out
SetTimeToLive	Set the time-to-live for the next datagram
ShowError	Display a message box with a description of the specified error
TraceRoute	Trace the route from the local system to a remote host

CIcmpClient::CIcmpClient Method

CIcmpClient();

The **CIcmpClient** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **IcmpInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[~CIcmpClient](#), [IsInitialized](#)

CIcmpClient::~~CIcmpClient

~CIcmpClient();

The **CIcmpClient** destructor releases resources allocated by the current instance of the **CIcmpClient** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CIcmpClient** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CIcmpClient](#)

CIcmpClient::AttachHandle Method

```
VOID AttachHandle(  
    HCLIENT hClient  
);
```

The **AttachHandle** method attaches the specified client handle to the current instance of the class.

Parameters

hClient

The handle to the client session that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a client handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that client session.

If a client handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous client session from being terminated, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hClient* parameter is presumed to be a valid client handle and no checks are performed to ensure that the handle is valid. Specifying an invalid client handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csicmv11.lib

See Also

[AttachThread](#), [DetachHandle](#), [GetHandle](#)

CIcmpClient::AttachThread Method

```
DWORD AttachThread(  
    DWORD dwThreadId  
);
```

The **AttachThread** method attaches the specified client handle to another thread.

Parameters

dwThreadId

The ID of the thread that will become the new owner of the handle. A value of zero specifies that the current thread should become the owner of the client handle.

Return Value

If the method succeeds, the return value is the thread ID of the previous owner. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When a client handle is created, it is associated with the current thread that created it. Normally, if another thread attempts to perform an operation using that handle, an error is returned since it does not own the handle. This is used to ensure that other threads cannot interfere with an operation being performed by the owner thread. In some cases, it may be desirable for one thread in a client application to create the client handle, and then pass that handle to another worker thread. The **AttachThread** method can be used to change the ownership of the handle to the new worker thread. By preserving the return value from the method, the original owner of the handle can be restored before the worker thread terminates.

This method should be called by the new thread immediately after it has been created, and if the new thread does not release the handle itself, the ownership of the handle should be restored to the parent thread before it terminates. Under no circumstances should **AttachThread** be used to forcibly release a handle allocated by another thread while a blocking operation is in progress. To cancel an operation, use the **Cancel** method and then release the handle after the blocking method exits and control is returned to the current thread.

Note that the *dwThreadId* parameter is presumed to be a valid thread ID and no checks are performed to ensure that the thread actually exists. Specifying an invalid thread ID will orphan the client handle used by the class until the destructor is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[AttachHandle](#), [Cancel](#), [CloseHandle](#), [CreateHandle](#), [DetachHandle](#), [GetHandle](#)

CIcmpClient::Cancel Method

INT Cancel();

The **Cancel** method cancels any outstanding blocking operation in the client, causing the blocking method to fail. The application may then retry the operation or terminate the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When the **Cancel** method is called, the blocking method will not immediately fail. An internal flag is set which causes the blocking operation to exit with an error. This means that the application cannot cancel an operation and immediately perform some other operation. Instead it must allow the calling stack to unwind, returning back to the blocking operation before making any further function calls.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[IsBlocking](#)

CIcmpClient::CloseHandle Method

```
INT CloseHandle(  
    HCLIENT hClient  
);
```

The **CloseHandle** method closes the socket and releases the memory allocated for the client session.

Parameters

hClient

A handle to the client session.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

[CIcmpClient](#), [CreateHandle](#)

ICmpClient::CreateHandle Method

```
HCLIENT CreateHandle(  
    UINT nPacketSize,  
    UINT nTimeToLive,  
    DWORD dwTimeout,  
    DWORD dwReserved,  
    HWND hEventWnd,  
    UINT uEventMsg  
);
```

The **CreateHandle** method creates a client handle for sending and receiving ICMP echo datagrams. If an event notification window is specified, the client will be notified when a network event occurs.

Parameters

nPacketSize

An unsigned integer which specifies the default packet size used when generating ICMP echo datagrams. The minimum packet size is 32 bytes and the maximum size is 65,535 bytes.

nTimeToLive

An unsigned integer which specifies the default time-to-live for ICMP echo datagrams. This determines the maximum number of times that a packet will be routed from one system to another while en route to its destination. The minimum time-to-live value is 1, the maximum is 255. The recommend value for this parameter is 255, and typical applications should use a time-to-live value of at least 30.

dwTimeout

An unsigned integer which specifies the maximum number of milliseconds to wait before the current operation times out.

dwReserved

A reserved parameter. This value should always be zero.

hEventWnd

The handle to an asynchronous notification window. This window receives messages which notify the client when asynchronous network events occur. If asynchronous event notification is not required, this parameter may be NULL.

uEventMsg

The message identifier that is used when an asynchronous network event occurs. This value should be greater than WM_USER as defined in the Windows header files. If the *hEventWnd* parameter is NULL, this parameter should be specified as WM_NULL.

Return Value

If the method succeeds, the return value is a handle to the client session. If the method fails, the return value is INVALID_CLIENT. To get extended error information, call **GetLastError**.

Remarks

The **CreateHandle** method creates a client handle that is used with subsequent calls to the library. This library uses a special type of socket called a raw socket, which is created to send and receive ICMP echo datagrams. Raw socket support is optional under the Windows Sockets specification, and may not be available if a non-standard networking libraries are used or may only be available to privileged accounts.

If the ***hEventWnd*** parameter is not NULL, the client operates in asynchronous mode and messages will be posted to the notification window when a network event occurs. When a message is posted to the window, the low word of the ***lParam*** parameter contains the event identifier. The high word of ***lParam*** contains the low word of the error code, if an error has occurred. The ***wParam*** parameter contains the client handle. One or more of the following event identifiers may be sent:

Value	Description
ICMP_EVENT_ECHO	The client has generated an ICMP echo datagram and has sent it to the specified host. If the datagram is received, the remote host should generate a reply and return it to the sender.
ICMP_EVENT_REPLY	The client has received an ICMP echo reply datagram from the remote host. At this point the client can collect statistical information.
ICMP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation.
ICMP_EVENT_CANCEL	The current operation has been canceled. The client application may attempt to retry the operation or close the handle.

To cancel asynchronous notification and return the client to a blocking mode, use the **DisableEvents** method.

The ability to create and send ICMP echo datagrams is limited to privileged users. Non-administrator users will receive an error if they attempt to create a client handle. On Windows NT it is possible to disable this security check by creating or modifying the system registry. Microsoft Knowledge Base article 195445 has additional information and instructions for making this change.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Sockets 2.0 update or later.

Header File: ctools11.h

Import Library: csicmv11.lib

[CicmpClient](#), [CloseHandle](#)

CIcmpClient::DetachHandle Method

HCLIENT DetachHandle();

The **DetachHandle** method detaches the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value `INVALID_CLIENT` will be returned.

Remarks

This method is used to detach a client handle created by the class for use with the SocketTools API. Once the client handle is detached from the class, no other class member functions may be called. Note that the handle must be explicitly released at some later point by the process or a resource leak will occur.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csicmv11.lib`

See Also

[AttachHandle](#), [GetHandle](#)

CIcmpClient::DisableEvents Method

INT DisableEvents();

The **DisableEvents** method disables the event notification mechanism, preventing subsequent event notification messages from being posted to the application's message queue.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **DisableEvents** method is used to disable event message posting for the specified client session. Although this will immediately prevent any new events from being generated, it is possible that messages could be waiting in the message queue. Therefore, an application must be prepared to handle client event messages after this method has been called.

This method is automatically called if the client has event notification enabled, and the **Disconnect** method is called. The same issues regarding outstanding event messages also applies in this situation, requiring that the application handle event messages that may reference a client handle that is no longer valid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

[EnableTrace](#)

CIcmpClient::Echo Method

```
INT Echo(  
    LPCTSTR lpszHostName,  
    UINT nIterations,  
    UINT nPacketSize,  
    DWORD dwTimeout,  
    LPICMPTIME lpTime  
);  
  
INT Echo(  
    LPCTSTR lpszHostName,  
    LPICMPTIME lpTime  
);
```

The **Echo** method sends one or more ICMP echo datagrams, collecting information about the reliability and latency of a connection between the local and remote host.

Parameters

lpszHostName

A pointer to a string which specifies the fully qualified domain name of the remote host, or the IP address in dotted notation.

nIterations

An unsigned integer value which specifies the number of echo datagrams that will be sent to the remote host. The minimum value for this parameter is 1 and the maximum value is 512.

nPacketSize

An unsigned integer value which specifies the size of the echo datagram in bytes. The minimum size is 1 byte and the maximum size is 65,535 bytes. It is recommended that most applications use the minimum size of 32 bytes for this parameter.

dwTimeout

An unsigned integer which specifies the number of milliseconds the method will wait for a response to an echo datagram.

lpTime

A pointer to an [ICMPTIME](#) structure which will contain the minimum, maximum and average round trip times for the echo datagrams sent and received.

Return Value

If the method succeeds, the return value is the number of replies received from the remote host. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **Echo** method sends a series of ICMP echo datagrams to the specified host, providing a simplified interface for pinging a remote system. If the method returns the same value as the number of iterations, then replies were received for all of the echo datagrams that were sent. This would typically indicate that the client can establish a reliable connection to the server; the values returned in the ICMPTIME structure provide information on the latency between the two hosts. Higher average time values would indicate greater latency and reduced throughput between the systems. If the method returns a value less than the specified number of iterations, this indicates that replies were not received for one or more of the echo datagrams. This may indicate that there are problems routing data between the local and remote host. A return value of zero indicates that there was no response

to the echo datagrams. The remote host may not exist or may not be available.

The failure for a host to respond to an ICMP echo datagram may not indicate a problem with the remote system. In some cases, a router between the local and remote host may be malfunctioning or discarding the datagrams. Systems can also be configured to specifically ignore ICMP echo datagrams and not respond to them; this is often a security measure to prevent certain kinds of Denial of Service attacks.

The ability to send ICMP datagrams may be restricted to users with administrative privileges, depending on the policies and configuration of the local system. If you are unable to send or receive any ICMP datagrams, it is recommended that you check the firewall settings and any third-party security software that could impact the normal operation of this component.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

CIcmpClient::EnableEvents Method

```
INT EnableEvents(  
    HWND hEventWnd,  
    UINT uEventMsg  
);
```

The **EnableEvents** method enables event notifications using Windows messages.

This method has been deprecated and may be unavailable in future releases. It was designed for use in legacy single-threaded applications and requires the application to have a message pump to process event messages. It should not be used with applications which are designed to execute as a service or those which do not have a graphical user interface.

Applications should use the **RegisterEvent** method to register an event handler which is invoked when an event occurs.

Parameters

- hEventWnd**
- Handle to the window which will receive the client notification messages. This parameter must specify a valid window handle. If a NULL handle is specified, event notification will be disabled.
- uEventMsg**
- The message that is received when a client event occurs. This value must be greater than 1024.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **EnableEvents** method is used to request that notification messages be posted to the specified window whenever a client event occurs. This allows an application to monitor the status of different client operations, such as a file transfer.

The **wParam** argument will contain the client handle, the low word of the **lParam** argument will contain the event ID, and the high word will contain any error code. If no error has occurred, the high word will always have a value of zero. The following events may be generated:

Value	Description
ICMP_EVENT_ECHO	The client has generated an ICMP echo datagram and has sent it to the specified host. If the datagram is received, the remote host should generate a reply and return it to the sender.
ICMP_EVENT_REPLY	The client has received an ICMP echo reply datagram from the remote host. At this point the client can collect statistical information.
ICMP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
ICMP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.

To disable event notification, call the **DisableEvents** method.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csicmv11.lib

[DisableEvents](#), [RegisterEvent](#)

CIcmpClient::EnableTrace Method

```
BOOL EnableTrace(  
    LPCTSTR lpszTraceFile,  
    DWORD dwTraceFlags  
);
```

The **EnableTrace** method enables the logging of socket function calls to a file.

Parameters

lpszTraceFile

A pointer to a string which specifies the name of the trace log file. If this parameter is NULL or an empty string, the default file name **cstrace.log** is used. The file is stored in the directory specified by the TEMP environment variable, if it is defined; otherwise, the current working directory is used.

dwTraceFlags

An unsigned integer that specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
TRACE_INFO	All function calls are written to the trace file. This is the default value.
TRACE_ERROR	Only those function calls which fail are recorded in the trace file.
TRACE_WARNING	Only those function calls which fail or return values which indicate a warning are recorded in the trace file.
TRACE_HEXDUMP	All functions calls are written to the trace file, plus all the data that is sent or received is displayed, in both ASCII and hexadecimal format.
TRACE_PROCESS	All function calls in the current process are logged, rather than only those functions in the current thread. This option is useful for multithreaded applications that are using worker threads.

Return Value

If the method succeeds, the return value is non-zero. A return value of zero indicates an error. Failure typically indicates that the tracing library **cstrcv11.dll** cannot be loaded on the local system.

Remarks

When trace logging is enabled, the file is opened, appended to and closed for each socket function call. This makes it possible for an application to append its own logging information, however care should be taken to ensure that the file is closed before the next network operation is performed. To limit the size of the log files, enable and disable logging only around those sections of code that you wish to trace.

Note that the TRACE_HEXDUMP trace level generates very large log files since it includes all of the data exchanged between your application and the remote host.

Trace method logging is managed on a per-thread basis, not for each client handle. This means that all SocketTools libraries and components share the same settings in the current thread. If you are using multiple SocketTools libraries or components in your application, you only need to enable logging once.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

[DisableTrace](#)

CicmpClient::FormatAddress Method

```
INT FormatAddress(  
    DWORD dwAddress,  
    LPTSTR lpszAddress,  
    INT nMaxLength  
);  
  
INT FormatAddress(  
    DWORD dwAddress,  
    CString& strAddress  
);
```

The **FormatAddress** method converts a numeric IP address to a null-terminated string.

Parameters

dwAddress

A unsigned 32-bit integer which specifies the IP address to be converted into a string.

lpszAddress

A pointer to a null-terminated array of characters which will contain the converted IP address in dot-notation. This string should be at least 16 characters in length. An alternate form of this method accepts a **CString** object which will contain the IP address in dotted notation when the method returns.

nMaxLength

The maximum number of characters which may be copied in to the string buffer.

Return Value

If the method succeeds, the return value is the length of the string buffer. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CIcmpClient::FreezeEvents Method

```
INT FreezeEvents(  
    BOOL bFreeze  
);
```

The **FreezeEvents** method is used to suspend and resume event handling by the client.

Parameters

bFreeze

A non-zero value specifies that event handling should be suspended by the client. A zero value specifies that event handling should be resumed.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

This method should be used when the application does not want to process events, such as when a modal dialog is being displayed. When events are suspended, all client events are queued. If events are re-enabled at a later point, those queued events will be sent to the application for processing. Note that only one of each event will be generated. For example, if the client has suspended event handling, and four read events occur, once event handling is resumed only one of those read events will be posted to the client. This prevents the application from being flooded by a potentially large number of queued events.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

CIcmpClient::GetErrorString Method

```
INT GetErrorString(  
    DWORD dwErrorCode,  
    LPTSTR lpszDescription,  
    INT cbDescription  
);  
  
INT GetErrorString(  
    DWORD dwErrorCode,  
    CString& strDescription  
);
```

The **GetErrorString** method is used to return a description of a specific error code. Typically this is used in conjunction with the **GetLastError** method for use with warning dialogs or as diagnostic messages.

Parameters

dwErrorCode

The error code for which a description is returned.

lpszDescription

A pointer to the buffer that will contain a description of the specified error code. This buffer should be at least 128 characters in length. An alternate form of the method accepts a **CString** variable which will contain the error description.

cbDescription

The maximum number of characters that may be copied into the description buffer.

Return Value

If the method succeeds, the return value is the length of the description string. If the method fails, the return value is zero, meaning that no description exists for the specified error code. Typically this indicates that the error code passed to the method is invalid.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

CicmpClient::GetFirstHost Method

```
BOOL GetFirstHost(  
    ICMPTRACE& icmpTrace  
);
```

The **GetFirstHost** method returns information about the first host between the local system and the remote host specified in the call to the **TraceRoute** method.

Parameters

icmpTrace

An [ICMPTRACE](#) structure which contains information about the intermediate host.

Return Value

If the method succeeds, the return value is non-zero. If the return value is zero, this indicates that no host information is available. To get extended error information, call **GetLastError**.

Remarks

The **GetFirstHost** method is used in conjunction with the **GetNextHost** method to enumerate all of the intermediate hosts between the local system and the remote host specified when the **TraceRoute** method was called.

Example

```
BOOL bResult = pClient->TraceRoute(strAddress);  
if (bResult)  
{  
    ICMPTRACE icmpTrace;  
  
    bResult = pClient->GetFirstHost(icmpTrace);  
    while (bResult)  
    {  
        // The icmpTrace structure contains information about the  
        // intermediate host in the traceroute  
        CString strHostName;  
        pClient->ResolveAddress(icmpTrace.dwHostAddress, strHostName);  
  
        bResult = pClient->GetNextHost(icmpTrace);  
    }  
}
```

Requirements

CIcmpClient::GetHandle Method

```
HCLIENT GetHandle();
```

The **GetHandle** method returns the client handle associated with the current instance of the class.

Parameters

None.

Return Value

This method returns the client handle associated with the current instance of the class object. If there is no active client session, the value INVALID_CLIENT will be returned.

Remarks

This method is used to obtain the client handle created by the class for use with the SocketTools API.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

```
INT GetHostAddress(  
    LPTSTR lpszHostAddress,  
    INT cbHostAddress  
);  
  
INT GetHostAddress(  
    CString& strHostAddress  
);
```

The **GetHostAddress** copies the IP address of the current host into the specified buffer as a string using dot-notation.

Parameters

lpszHostAddress

A pointer to the buffer that will contain the IP address of the current remote host in dot-notation. This buffer should be at least 16 characters in length.

cbHostAddress

The maximum number of characters that may be copied into the buffer, including the terminating null character character.

Return Value

If the method succeeds, the return value is the length of the address string. If the return value is zero, this indicates that no remote host has been specified. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

CicmpClient::GetHostName Method

```
INT GetHostName(  
    LPTSTR lpszHostName,  
    INT cbHostName  
);  
  
INT GetHostName(  
    CString& strHostName  
);
```

The **GetHostName** copies the name of the current host into the specified buffer.

Parameters

lpszHostName

A pointer to the buffer that will contain the name of the current remote host. This buffer should be at least 64 characters in length.

cbHostName

The maximum number of characters that may be copied into the buffer, including the terminating null character character.

Return Value

If the method succeeds, the return value is the length of the host name string. If the return value is zero, this indicates that no remote host has been specified. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

CIcmpClient::GetLastError Method

```
DWORD GetLastError();  
  
DWORD GetLastError(  
    CString& strDescription  
);
```

Parameters

strDescription

A string which will contain a description of the last error code value when the method returns. If no error has been set, or the last error code has been cleared, this string will be empty.

Return Value

The return value is the last error code value for the current thread. Functions set this value by calling the **SetLastError** method. The Return Value section of each reference page notes the conditions under which the method sets the last error code.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. You should call the **GetLastError** method immediately when a method's return value indicates that an error has occurred. That is because some methods call **SetLastError(0)** when they succeed, clearing the error code set by the most recently failed method.

Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or ICMP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

The description of the error code is the same string that is returned by the **GetErrorString** method.

Requirements

CIcmpClient::GetNextHost Method

```
BOOL GetFirstHost(  
    ICMPTRACE& icmpTrace  
);
```

The **GetNextHost** method returns information about the next host between the local system and the remote host specified in the call to the **TraceRoute** method.

Parameters

icmpTrace

An [ICMPTRACE](#) structure which contains information about the intermediate host.

Return Value

If the method succeeds, the return value is non-zero. If the return value is zero, this indicates that no host information is available. To get extended error information, call **GetLastError**.

Remarks

The **GetNextHost** method is used in conjunction with the **GetFirstHost** method to enumerate all of the intermediate hosts between the local system and the remote host specified when the **TraceRoute** method was called.

Example

```
BOOL bResult = pClient->TraceRoute(strAddress);  
if (bResult)  
{  
    ICMPTRACE icmpTrace;  
  
    bResult = pClient->GetFirstHost(icmpTrace);  
    while (bResult)  
    {  
        // The icmpTrace structure contains information about the  
        // intermediate host in the traceroute  
        CString strHostName;  
        pClient->ResolveAddress(icmpTrace.dwHostAddress, strHostName);  
  
        bResult = pClient->GetNextHost(icmpTrace);  
    }  
}
```

Requirements

The **GetSequenceId** method returns the sequence identifier for the last ICMP echo datagram received by the client.

Parameters

None.

Return Value

If the method succeeds, the return value is the sequence identifier. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

CIcmpClient::GetTimeout Method

INT GetTimeout();

The **GetTimeout** method returns the number of seconds the client will wait for a response from the remote host. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

None.

Return Value

If the method succeeds, the return value is the timeout period in seconds. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections. A value of zero indicates that the default timeout period of 20 seconds should be used.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[CreateHandle](#), [SetTimeout](#)

ICmpClient::GetTimeToLive Method

```
INT GetTimeToLive();
```

The **GetTimeToLive** method returns the time-to-live for the last ICMP echo datagram received by the client.

Parameters

None.

Return Value

If the method succeeds, the return value is the time-to-live for the last datagram. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The time-to-live (TTL) value is specified in the IP header of a datagram, and is used to control the number of routers that the datagram is passed through. Each router that handles the datagram decrements the TTL value by one. When it drops to zero, a datagram is returned to the sender, specifying that the TTL has been exceeded. The default value is 255.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

CIcmpClient::GetTripTime Method

```
INT GetTripTime(  
    LPICMP_TIME lpTime  
);
```

The **GetTripTime** returns round-trip statistics for the datagrams sent to the current remote host.

Parameters

lpTime

A pointer to an [ICMP_TIME](#) data structure which will contain the round-trip statistics for the current remote host.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is `ICMP_ERROR`. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: `cstools11.h`

Import Library: `csicmv11.lib`

See Also

CIcmpClient::IsBlocking Method

BOOL IsBlocking();

The **IsBlocking** method is used to determine if the client is currently performing a blocking operation.

Parameters

None.

Return Value

If the client is performing a blocking operation, the method returns a non-zero value. If the client is not performing a blocking operation, or the client handle is invalid, the method returns zero.

Remarks

Because a blocking operation can allow the application to be re-entered (for example, by pressing a button while the operation is being performed), it is possible that another blocking method may be called while it is in progress. Since only one thread of execution may perform a blocking operation at any one time, an error would occur. The **IsBlocking** method can be used to determine if the client is already blocked, and if so, take some other action (such as warning the user that they must wait for the operation to complete).

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Cancel](#), [IsInitialized](#)

CIcmpClient::IsInitialized Method

BOOL IsInitialized();

The **IsInitialized** method returns whether or not the class object has been successfully initialized.

Return Value

This method returns a non-zero value if the class object has been successfully initialized. A return value of zero indicates that the runtime license key could not be validated or the networking library could not be loaded by the current process.

Remarks

When an instance of the class is created, the class constructor will attempt to initialize the component with the runtime license key that was created when SocketTools was installed. If the constructor is unable to validate the license key or load the networking libraries, this initialization will fail.

If SocketTools was installed with an evaluation license, the application cannot be redistributed to another system. The class object will fail to initialize if the application is executed on another system, or if the evaluation period has expired. To redistribute your application, you must purchase a development license which will include the runtime key that is needed to redistribute your software to other systems. Refer to the Developer's Guide for more information.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

CIcmpClient::RecvEcho Method

INT RecvEcho();

The **RecvEcho** method reads the reply to an ICMP echo datagram generated by the client. This method should only be called by asynchronous client sessions in response to an event notification that a datagram has been received.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetRecvCount](#), [GetSequenceId](#), [GetTimeToLive](#), [SendEcho](#)

ICmpClient::RegisterEvent Method

```
INT RegisterEvent(  
    UINT nEventId,  
    ICMPEVENTPROC lpEventProc,  
    DWORD_PTR dwParam  
);
```

The **RegisterEvent** method registers an event handler for the specified event.

Parameters

nEventId

An unsigned integer which specifies which event should be registered with the specified callback function. One of the following values may be used:

Value	Description
ICMP_EVENT_ECHO	The client has generated an ICMP echo datagram and has sent it to the specified host. If the datagram is received, the remote host should generate a reply and return it to the sender.
ICMP_EVENT_REPLY	The client has received an ICMP echo reply datagram from the remote host. At this point the client can collect statistical information.
ICMP_EVENT_TIMEOUT	The network operation has exceeded the specified timeout period. The client application may attempt to retry the operation, or may disconnect from the server and report an error to the user.
ICMP_EVENT_CANCEL	The current operation has been canceled. Under most circumstances the client should disconnect from the server and re-connect if needed. After an operation has been canceled, the server may abort the connection or refuse to accept further commands from the client.

lpEventProc

Specifies the procedure-instance address of the application defined callback function. For more information about the callback function, see the description of the **IcmpEventProc** callback function. If this parameter is NULL, the callback for the specified event is disabled.

dwParam

A user-defined integer value that is passed to the callback function. If the application targets the x86 (32-bit) platform, this parameter must be a 32-bit unsigned integer. If the application targets the x64 (64-bit) platform, this parameter must be a 64-bit unsigned integer.

Remarks

The **RegisterEvent** method associates a callback function with a specific event. The event handler is an **IcmpEventProc** function that is invoked when the event occurs. Arguments are passed to the function to identify the client session, the event type and the user-defined value specified when the event handler is registered. If the event occurs because of an error condition, the error code will be provided to the handler.

The callback function specified by the *lpEventProc* parameter must be declared using the **__stdcall** calling convention. This ensures the arguments passed to the event handler are pushed on to the stack in the correct order. Failure to use the correct calling convention will corrupt the stack and cause the application to terminate abnormally.

The *dwParam* parameter is commonly used to identify the class instance which is associated with the event that has occurred. Applications will cast the **this** pointer to a DWORD_PTR value when calling this function, and then the event handler will cast it back to a pointer to the class instance. This gives the handler access to the class member variables and methods.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[DisableEvents](#), [EnableEvents](#), [FreezeEvents](#), [IcmpEventProc](#)

CIcmpClient::Reset Method

INT Reset();

The **Reset** method resets the client session, clearing the packet trip statistics, time-to-live, sequence identifier, send and receive counts.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[SetHostAddress](#), [SetHostName](#), [SetSequenceId](#), [SetTimeToLive](#)

CIcmpClient::ResolveAddress Method

```
INT ResolveAddress(  
    DWORD dwAddress,  
    LPTSTR lpszHostName,  
    INT nMaxLength  
);
```

```
INT ResolveAddress(  
    DWORD dwAddress,  
    CString& strHostName  
);
```

The **ResolveAddress** method resolves a numeric IP address into a fully qualified domain name.

Parameters

dwAddress

The IP address to be resolved, specified as an unsigned 32-bit integer in network byte order.

lpszHostName

A pointer to a buffer that will contain a null-terminated string that specifies the fully qualified domain name for the host. It is recommended that this buffer be at least 64 characters in length.

nMaxLength

The maximum number of characters that can be copied into the string buffer, including the terminating null character.

Return Value

If the method succeeds, the return value is the length of the host name. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **ResolveAddress** method is used to perform a reverse DNS lookup, converting a numeric IP address into a fully qualified domain name. This is useful for methods like **TraceRoute**, which return host addresses as numeric values in network byte order. If the reverse DNS lookup fails because there is no PTR record for the given IP address, a printable form of the address in dotted notation will be returned in the string buffer.

Calling this method will cause the thread to block until the IP address is resolved, or until the DNS query times out because there is no reverse record for the address. In some cases, a reverse lookup can take several seconds.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetHostAddress](#), [GetHostName](#), [SetHostAddress](#), [SetHostName](#), [TraceRoute](#)

CicmpClient::SendEcho Method

INT SendEcho();

The **SendEcho** method sends an ICMP echo datagram to the remote host.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

For asynchronous client sessions, this method returns immediately. Otherwise, the client enters a blocking state and waits for a reply from the remote host. The method returns when a reply has been received, or the operation times-out.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

ICmpClient::SetHostAddress Method

```
INT SetHostAddress(  
    DWORD dwAddress  
);  
  
INT SetHostAddress(  
    LPCTSTR lpszAddress  
);
```

The **SetHostAddress** method specifies the IP address of the host to receive an ICMP echo datagram. If the address specifies a new host, the current client statistics are reset.

Parameters

dwAddress

The IP address of the remote host as a 32-bit integer value, specified in network byte order. In an alternate form of this method, a pointer to a string which specifies the IP address in dotted notation may also be used.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

To specify a remote host name, use the **SetHostName** method instead.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetHostAddress](#), [GetHostName](#), [SetHostName](#)

CicmpClient::SetHostName Method

```
INT SetHostName(  
    HCLIENT hClient,  
    LPCTSTR lpszHostName  
);
```

The **SetHostName** method specifies the name of the host to receive an ICMP echo datagram. If the name specifies a new host, the current client statistics are reset.

Parameters

hClient

A handle to the client session.

lpszHostName

A pointer to a string which specifies the name, or IP address in dot-notation, of the remote host.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetHostAddress](#), [GetHostName](#), [SetHostAddress](#)

ICmpClient::SetLastError Method

```
VOID SetLastError(  
    DWORD dwErrorCode  
);
```

The **SetLastError** method sets the last error code for the current thread. This method is typically used to clear the last error by specifying a value of zero as the parameter.

Parameters

dwErrorCode

Specifies the last error code for the current thread.

Return Value

None.

Remarks

Error codes are unsigned 32-bit values which are private to each calling thread. Most methods will set the last error code value when they fail; a few methods set it when they succeed. Function failure is typically indicated by a return value such as FALSE, NULL, INVALID_CLIENT or ICMP_ERROR. Those methods which call **SetLastError** when they succeed are noted on the method reference page.

Applications can retrieve the value saved by this method by using the **GetLastError** method. The use of **GetLastError** is optional; an application can call the method to determine the specific reason for a method failure.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetErrorString](#), [GetLastError](#), [ShowError](#)

CIcmpClient::SetPacketSize Method

```
UINT SetPacketSize(  
    UINT nPacketSize  
);
```

The **SetPacketSize** method sets the size of the ICMP datagram packet that is sent to the remote host.

Parameters

nPacketSize

Size of the ICMP datagram packet in bytes. The minimum packet size is 1 byte and the maximum packet size is 65,535 bytes.

Return Value

If the method succeeds, the return value is the previous ICMP datagram packet size. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

Note that packet sizes over 512 bytes may not be supported by your networking software or configuration. It is recommended that most applications use the minimum packet size of 32 bytes.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetPacketSize](#), [SetSequenceId](#), [SetTimeToLive](#)

CIcmpClient::SetSequenceId Method

```
INT SetSequenceId(  
    INT nSequenceId  
);
```

The **SetSequenceId** method sets the sequence identifier for the next ICMP echo datagram sent by the client. The default sequence identifier for the first datagram is one.

Parameters

nSequenceId

The sequence identifier for the next datagram sent by the client.

Return Value

If the method succeeds, the return value is the previous sequence identifier. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

CIcmpClient::SetTimeout Method

```
INT SetTimeout(  
    UINT nTimeout  
);
```

The **SetTimeout** method sets the number of seconds the client will wait for a response from the remote host. Once the specified number of seconds has elapsed, the method will fail and return to the caller.

Parameters

nTimeout

The number of seconds to wait for a blocking operation to complete.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The timeout value is only used with blocking client connections.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

See Also

[GetTimeout](#)

CIcmpClient::SetTimeToLive Method

```
INT SetTimeToLive(  
    INT nTimeToLive  
);
```

The **SetTimeToLive** method sets the maximum time-to-live for the next ICMP datagram sent by the client.

Parameters

nTimeToLive

The time-to-live value for the next ICMP echo datagram.

Return Value

If the method succeeds, the return value is the previous time-to-live value. If the method fails, the return value is ICMP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The time-to-live (TTL) value is specified in the IP header of a datagram, and is used to control the number of routers that the datagram is passed through. Each router that handles the datagram decrements the TTL value by one. When it drops to zero, a datagram is returned to the sender, specifying that the TTL has been exceeded.

Calling this method changes the default TTL value for all subsequent ICMP datagrams sent by the library, with the default value being 255. Note that not all Windows Sockets implementations support setting the time-to-live value.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

CicmpClient::ShowError Method

```
INT ShowError(  
    LPCTSTR lpszAppTitle,  
    UINT uType,  
    DWORD dwErrorCode  
);
```

The **ShowError** method displays a message box which describes the specified error.

Parameters

lpszAppTitle

A pointer to a string which specifies the title of the message box that is displayed. If this argument is NULL or omitted, then the default title of "Error" will be displayed.

uType

An unsigned integer which specifies the type of message box that will be displayed. This is the same value that is used by the **MessageBox** method in the Windows API. If a value of zero is specified, then a message box with a single OK button will be displayed. Refer to that method for a complete list of options.

dwErrorCode

Specifies the error code that will be used when displaying the message box. If this argument is zero, then the last error that occurred in the current thread will be displayed.

Return Value

If the method is successful, the return value will be the return value from the **MessageBox** function. If the method fails, it will return a value of zero.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csicmv11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[GetErrorString](#), [GetLastError](#), [SetLastError](#)

CIcmpClient::TraceRoute Method

```
BOOL TraceRoute(  
    LPCTSTR lpszHostName,  
    UINT nMaxHops,  
    DWORD dwTimeout  
);
```

The **TraceRoute** method sends a series of ICMP echo datagrams to trace the route taken from the local system to the remote host.

Parameters

lpszHostName

A pointer to a string which specifies the fully qualified domain name of the remote host, or the IP address in dotted notation.

nMaxHops

An unsigned integer which specifies the maximum number of routers the datagram will be forwarded through (the number of hops) to the remote host. The minimum value is 1 and the maximum value is 255. It is recommended that most applications specify a value of at least 30.

dwTimeout

An unsigned integer which specifies the number of milliseconds the method will wait for a response to an echo datagram.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

The **TraceRoute** method sends a series of ICMP echo datagrams to the specified host, adjusting the time-to-live value to determine the intermediate hosts that route the packet. Use the **GetFirstHost** and **GetNextHost** methods to enumerate the hosts returned by the method.

It is important to note that the failure of an intermediate host to respond to an ICMP echo datagram may not indicate a problem with the remote system. Systems can be configured to specifically ignore ICMP echo datagrams and not respond to them; this is often a security measure to prevent certain kinds of Denial of Service attacks.

The ability to send ICMP datagrams may be restricted to users with administrative privileges, depending on the policies and configuration of the local system. If you are unable to send or receive any ICMP datagrams, it is recommended that you check the firewall settings and any third-party security software that could impact the normal operation of this component.

Example

```
BOOL bResult = pClient->TraceRoute(strAddress);  
if (bResult)  
{  
    ICMPTRACE icmpTrace;  
  
    bResult = pClient->GetFirstHost(icmpTrace);  
    while (bResult)  
    {  
        // The icmpTrace structure contains information about the
```

```
        // intermediate host in the traceroute
        CString strHostName;
        pClient->ResolveAddress(icmpTrace.dwHostAddress, strHostName);

        bResult = pClient->GetNextHost(icmpTrace);
    }
}
```

Requirements

Internet Control Message Protocol Data Structures

- ICMPTIME
- ICMPTRACE
- INTERNET_ADDRESS
- SYSTEMTIME

ICMPTIME

This structure is used by the [GetTripTime](#) method to return the round-trip times of an ICMP datagram.

```
typedef struct _ICMPTIME {  
    DWORD dwTripAverage;  
    DWORD dwTripMaximum;  
    DWORD dwTripMinimum;  
    DWORD dwTripTime;  
} ICMPTIME, *LPICMPTIME;
```

Members

dwTripAverage

The average round-trip time in milliseconds for all datagrams sent to the current host.

dwTripMaximum

The maximum round-trip time in milliseconds for all datagrams sent to current host.

dwTripMinimum

The minimum round-trip time in milliseconds for all datagrams sent to the current host.

dwTripTime

The current round-trip time in milliseconds for the last datagram sent to the current host.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

ICMPTRACE

This structure is used by the [GetFirstHost](#) and [GetNextHost](#) methods to return the route of an ICMP datagram.

```
typedef struct _ICMPTRACE
{
    UINT        nDistance;
    DWORD       dwHostAddress;
    DWORD       dwTripAverage;
    DWORD       dwTripMaximum;
    DWORD       dwTripMinimum;
} ICMPTRACE, *LPICMPTRACE;
```

Members

nDistance

The distance from the local host to the remote host for this route.

dwHostAddress

An unsigned integer which specifies the IP address of the remote host in network byte order.

dwTripAverage

The average round-trip time in milliseconds for all datagrams sent to the specified host.

dwTripMaximum

The maximum round-trip time in milliseconds for all datagrams sent to specified host.

dwTripMinimum

The minimum round-trip time in milliseconds for all datagrams sent to the specified host.

dwTripTime

The current round-trip time in milliseconds for the last datagram sent to the specified host.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

INTERNET_ADDRESS

This structure represents a numeric IPv4 or IPv6 address in network byte order.

```
typedef struct _INTERNET_ADDRESS
{
    INT      ipFamily;
    BYTE     ipNumber[16];
} INTERNET_ADDRESS, *LPINTERNET_ADDRESS;
```

Members

ipFamily

An integer which identifies the type of IP address. It will be one of the following values:

Value	Description
INET_ADDRESS_UNKNOWN	The address has not been specified or the bytes in the <i>ipNumber</i> array does not represent a valid address. Functions which populate this structure will use this value to indicate that the address cannot be determined.
INET_ADDRESS_IPV4	Specifies that the address is in IPv4 format. The first four bytes of the <i>ipNumber</i> array are significant and contains the IP address. The remaining bytes are not significant and an application should not depend on them having any particular value, including zero.
INET_ADDRESS_IPV6	Specifies that the address is in IPv6 format. All bytes in the <i>ipNumber</i> array are significant. Note that it is possible for an IPv6 address to actually represent an IPv4 address. This is indicated by the first 10 bytes of the address being zero.

ipNumber

A byte array which contains the numeric form of the IP address. This array is large enough to store both IPv4 (32 bit) and IPv6 (128 bit) addresses. The values are stored in network byte order.

Remarks

The **INTERNET_ADDRESS** structure is used by some functions to represent an Internet address in a binary format that is compatible with both IPv4 and IPv6 addresses. Applications that use this structure should consider it to be opaque, and should not modify the contents of the structure directly.

For compatibility with legacy applications that expect an IP address to be 32 bits and stored in an unsigned integer, you can copy the first four bytes of the *ipNumber* array using the **CopyMemory** function or equivalent. Note that if this is done, your application should always check the *ipFamily* member first to make sure that it is actually an IPv4 address.

Requirements

- Minimum Desktop Platform:** Windows 7 Service Pack 1
- Minimum Server Platform:** Windows Server 2008 R2 Service Pack 1
- Header File:** ctools11.h

SYSTEMTIME

The **SYSTEMTIME** structure represents a date and time using individual members for the month, day, year, weekday, hour, minute, second, and millisecond.

```
typedef struct _SYSTEMTIME
{
    WORD wYear;
    WORD wMonth;
    WORD wDayOfWeek;
    WORD wDay;
    WORD wHour;
    WORD wMinute;
    WORD wSecond;
    WORD wMilliseconds;
} SYSTEMTIME, *LPSYSTEMTIME;
```

Members

wYear

Specifies the current year. The year value must be greater than 1601.

wMonth

Specifies the current month. January is 1, February is 2 and so on.

wDayOfWeek

Specifies the current day of the week. Sunday is 0, Monday is 1 and so on.

wDay

Specifies the current day of the month

wHour

Specifies the current hour.

wMinute

Specifies the current minute

wSecond

Specifies the current second.

wMilliseconds

Specifies the current millisecond.

Requirements

Library Information

Class Name	CImapClient
File Name	CSMAPV11.DLL
Version	11.0.2218.1855
LibID	FFDFB6F8-6CBE-49EF-8C0F-093254490868
Import Library	CSMAPV11.LIB
Dependencies	None
Standards	RFC 3501

Overview

The Internet Message Access Protocol (IMAP) is an application protocol which is used to access a user's email messages which are stored on a mail server. However, unlike the Post Office Protocol (POP) where messages are downloaded and processed on the local system, the messages on an IMAP server are retained on the server and processed remotely. This is ideal for users who need access to a centralized store of messages or have limited bandwidth. For example, traveling salesmen who have notebook computers or mobile users on a wireless network would be ideal candidates for using IMAP.

The SocketTools IMAP library implements the current standard for this protocol, and provides methods to retrieve messages, or just certain parts of a message, create and manage mailboxes, search for specific messages based on certain criteria and so on. The API is designed as a superset of the Post Office Protocol API, so developers who are used to working with the POP3 library will find the IMAP library very easy to integrate into an existing application.

This library supports secure connections using the TLS protocol.

Requirements

The SocketTools Library Edition libraries are compatible with any programming language which supports calling functions exported from a standard dynamic link library (DLL). If you are using Visual C++ 6.0 it is required that you have Service Pack 6 (SP6) installed. You should install all updates for your development tools and have the current Windows SDK installed. The minimum recommended version of Visual Studio is Visual Studio 2010.

This library is supported on Windows 7, Windows Server 2008 R2 and later versions of the desktop and server platforms. If you are using Windows 7, you must have Service Pack 1 (SP1) installed as a minimum requirement. It is recommended that you install the current service pack and all critical updates available for your version of the operating system.

This product includes both 32-bit and 64-bit libraries. Native 64-bit CPU support requires the 64-bit version of Windows 7 or later versions of the Windows operating system.

Distribution

When you distribute your application that uses this library, it is recommended that you install the file in the same folder as your application executable. If you install the library into a shared location on the system, it is important that you distribute the correct version for the target platform and it should be registered as a shared DLL. This is a standard Windows dynamic link library, not an ActiveX component, and does not require COM registration.

Internet Message Access Protocol Class Methods

Class	Description
CImapClient	Constructor which initializes the current instance of the class
~CImapClient	Destructor which releases resources allocated by the class
Method	Description
AttachHandle	Attach the specified client handle to this instance of the class
AttachThread	Attach the specified client handle to another thread
Cancel	Cancel the current blocking operation
CheckMailbox	Check the current mailbox for new messages
CloseMessage	Close the current message
Command	Send a command to the server
Connect	Connect to the specified server
CopyMessage	Copy a message from the current mailbox to another mailbox
CreateMailbox	Create a new mailbox on the server
CreateMessage	Create a new message in the specified mailbox
CreateSecurityCredentials	Allocate a structure to establish client security credentials
DecodeMailboxName	Decode a UTF-7 encoded mailbox name using the specified code page
DeleteMailbox	Delete the specified mailbox from the server
DeleteMessage	Delete the specified message from the mailbox
DeleteSecurityCredentials	Delete the specified client security credentials
DetachHandle	Detach the handle for the current instance of this class
DisableEvents	Disable the event notification mechanism
DisableTrace	Disable logging of network function calls to the trace log
Disconnect	Disconnect from the current server
EnableEvents	Enable the client event notification mechanism
EnableTrace	Enable logging of network function calls to a file
EncodeMailboxName	Encode a mailbox name using modified UTF-7 encoding
EnumMessages	Enumerate the messages in the current mailbox
ExamineMailbox	Select the specified mailbox in read-only mode
ExpungeMailbox	Remove messages that have been marked for deletion from the current mailbox
FreezeEvents	Suspend and resume event handling by the client
GetCapability	Return a string which identifies the capabilities of the server
GetCurrentMailbox	Return the name of the currently selected mailbox

GetDeletedMessages	Return the messages that have been marked for deletion
GetErrorString	Return a description for the specified error code
GetFirstMailbox	Return the first mailbox according to specified criteria
GetHandle	Return the client handle used by this instance of the class
GetHeaderValue	Return the value of the specified header field
GetIdleThreadId	Return the ID of the thread created to monitor the client session
GetLastError	Return the last error code
GetMailboxDelimiter	Get the path delimiter for the specified mailbox hierarchy
GetMailboxSize	Return the size of the specified mailbox
GetMailboxStatus	Return the status of the specified mailbox
GetMailboxUID	Return the unique identifier for the specified mailbox
GetMessage	Retrieve the specified message from the server
GetMessageCount	Return the number of messages available in the mailbox
GetMessageFlags	Return the status flags for the specified message
GetMessageHeaders	Retrieve the specified message header from the server
GetMessageId	Return the message ID string for the specified message
GetMessageParts	Return the number of MIME message parts in the specified message
GetMessageSender	Return the address of the message sender
GetMessageSize	Return the size of the specified message
GetMessageUID	Return the unique identifier for the specified message
GetNewMessages	Return a list of the new messages in the current mailbox
GetNextMailbox	Return the next mailbox name on the server
GetResultCode	Return the result code from the previous command
GetResultString	Return the result string from the previous command
GetSecurityInformation	Return security information about the current client connection
GetStatus	Return the current status of the client
GetTimeout	Return the number of seconds until an operation times out
GetTransferStatus	Return data transfer statistics
GetUnseenMessages	Return a list of messages from the current mailbox that have not been read
Idle	Enables mailbox status monitoring for the client session
ImapEventProc	Callback method that processes events generated by the client
ImapIdleProc	Callback function that receives update notifications from the server
IsBlocking	Determine if the client is blocked, waiting for information
IsConnected	Determine if the client is connected to the server
IsInitialized	Determine if the class has been successfully initialized

IsReadable	Determine if data can be read from the server
IsWritable	Determine if data can be written to the server
Login	Login to the server
OpenMessage	Open the specified message for reading on the server
Read	Read data returned by the server
RegisterEvent	Register an event handler for the specified event
RenameMailbox	Rename the specified mailbox
ReselectMailbox	Reselect the current mailbox and return updated status information
SearchMailbox	Search the mailbox according to specified criteria
SelectMailbox	Select the specified mailbox in read-write mode
SetLastError	Set the last error code for the current thread
SetMessageFlags	Set one or more status flags for the specified message
SetTimeout	Set the number of seconds until an operation times out
ShowError	Display a message box with a description of the specified error
StoreMessage	Store the contents of a message to the specified file
SubscribeMailbox	Subscribe to the specified mailbox
UndeleteMessage	Undelete the specified message from the current mailbox
UnselectMailbox	Unselect the current mailbox and expunge any deleted messages
UnsubscribeMailbox	Unsubscribe from the specified mailbox
Write	Write data to the server

CImapClient::CImapClient Method

CImapClient();

The **CImapClient** constructor initializes the class library and validates the license key at runtime.

Remarks

If the constructor fails to validate the runtime license, subsequent methods in this class will fail. If the product is installed with an evaluation license, then the application will only function on the development system and cannot be redistributed.

The constructor calls the **ImapInitialize** function to initialize the library, which dynamically loads other system libraries and allocates thread local storage. If you are using this class within another DLL, it is important that you do not create or destroy an instance of the class from within the **DllMain** function because it can result in deadlocks or access violation errors. You should not declare static or global instances of this class within another DLL if it is linked with the C runtime library (CRT) because it will automatically call the constructors and destructors for static and global C++ objects and has the same restrictions.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csmapi11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[~CImapClient](#), [IsInitialized](#)

CImapClient::~CImapClient

`~CImapClient();`

The **CImapClient** destructor releases resources allocated by the current instance of the **CImapClient** object. It also uninitializes the library if there are no other concurrent uses of the class.

Remarks

When a **CImapClient** object goes out of scope, the destructor is automatically called to allow the library to free any resources allocated on behalf of the process. Any pending blocking or asynchronous calls in this process are canceled without posting any notification messages, and all handles that were created for the client session are destroyed.

The destructor is not called explicitly by the application.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

Unicode: Implemented as Unicode and ANSI versions

[CImapClient](#)

CImapClient::AttachHandle Method

```
VOID AttachHandle(  
    HCLIENT hClient  
);
```

The **AttachHandle** method attaches the specified client handle to the current instance of the class.

Parameters

hClient

The handle to the client session that will be attached to the current instance of the class object.

Return Value

None.

Remarks

This method is used to attach a client handle created outside of the class using the SocketTools API. Once the client handle is attached to the class, the other class member functions may be used with that client session.

If a client handle already has been created for the class, that handle will be released when the new handle is attached to the class object. If you want to prevent the previous client session from being terminated, you must call the **DetachHandle** method. Failure to release the detached handle may result in a resource leak in your application.

Note that the *hClient* parameter is presumed to be a valid client handle and no checks are performed to ensure that the handle is valid. Specifying an invalid client handle will cause subsequent method calls to fail.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csmapv11.lib

See Also

[AttachThread](#), [DetachHandle](#), [GetHandle](#)

CImapClient::AttachThread Method

```
DWORD AttachThread(  
    DWORD dwThreadId  
);
```

The **AttachThread** method attaches the specified client handle to another thread.

Parameters

dwThreadId

The ID of the thread that will become the new owner of the handle. A value of zero specifies that the current thread should become the owner of the client handle.

Return Value

If the method succeeds, the return value is the thread ID of the previous owner. If the method fails, the return value is IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When a client handle is created, it is associated with the current thread that created it. Normally, if another thread attempts to perform an operation using that handle, an error is returned since it does not own the handle. This is used to ensure that other threads cannot interfere with an operation being performed by the owner thread. In some cases, it may be desirable for one thread in a client application to create the client handle, and then pass that handle to another worker thread. The **AttachThread** method can be used to change the ownership of the handle to the new worker thread. By preserving the return value from the method, the original owner of the handle can be restored before the worker thread terminates.

This method should be called by the new thread immediately after it has been created, and if the new thread does not release the handle itself, the ownership of the handle should be restored to the parent thread before it terminates. Under no circumstances should **AttachThread** be used to forcibly release a handle allocated by another thread while a blocking operation is in progress. To cancel an operation, use the **Cancel** method and then release the handle after the blocking method exits and control is returned to the current thread.

Note that the *dwThreadId* parameter is presumed to be a valid thread ID and no checks are performed to ensure that the thread actually exists. Specifying an invalid thread ID will orphan the client handle used by the class until the destructor is called.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapv11.lib

See Also

[AttachHandle](#), [Cancel](#), [Connect](#), [DetachHandle](#), [Disconnect](#), [GetHandle](#)

CImapClient::Cancel Method

INT **Cancel()**;

The **Cancel** method cancels any outstanding blocking operation in the client, causing the blocking method to fail. The application may then retry the operation or terminate the client session.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When the **Cancel** method is called, the blocking method will not immediately fail. An internal flag is set which causes the blocking operation to exit with an error. This means that the application cannot cancel an operation and immediately perform some other operation. Instead it must allow the calling stack to unwind, returning back to the blocking operation before making any further function calls.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

[IsBlocking](#)

CImapClient::CheckMailbox Method

```
INT CheckMailbox(  
    UINT *LpnMessages,  
    UINT *LpnUnseen  
);
```

The **CheckMailbox** method requests that the server create a checkpoint of the currently selected mailbox, and returns the current number of messages and unseen messages.

Parameters

LpnMessages

A pointer to an unsigned integer value which will contain the number of messages in the currently selected mailbox when the method returns.

LpnUnseen

A pointer to an unsigned integer value which will contain the number of unseen messages in the currently selected mailbox.

Return Value

If the method succeeds, it returns zero. If an error occurs, the method returns IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

When the client requests a checkpoint, the server may perform implementation-dependent housekeeping for that mailbox, such as updating the mailbox on disk with the current state of the mailbox in memory. On some systems this command has no effect other than to update the client with the current number of messages in the mailbox.

This method actually sends two IMAP commands. The first is the CHECK command, followed by the NOOP command to poll for any new messages that have arrived. In addition to polling the server for new messages, this command can also be used to ensure the idle timer on the server does not expire and force a disconnect from the client.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapv11.lib

See Also

[CreateMailbox](#), [GetFirstMailbox](#), [GetMailboxStatus](#), [GetNextMailbox](#), [RenameMailbox](#)

CImapClient::CloseMessage Method

INT CloseMessage();

The **CloseMessage** method closes the current message.

Parameters

None.

Return Value

If the method succeeds, the return value is zero. If the method fails, the return value is IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

The **CloseMessage** method closes the current message. If there is any remaining data left to be read from the message, it will be read and discarded.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

[CreateMessage](#), [OpenMessage](#)

CImapClient::Command Method

```
INT Command(  
    LPCTSTR lpszCommand,  
    LPCTSTR lpszParameter  
);
```

The **Command** method sends a command to the server. This method is typically used for site-specific commands not directly supported by the API.

Parameters

lpszCommand

The command which will be executed by the server.

lpszParameter

An optional command parameter. If the command requires more than one parameter, then they should be combined into a single string, with a space separating each parameter. If the command does not accept any parameters, this value may be NULL.

Return Value

If the method succeeds, it returns an IMAP result code. If the command was successful, it returns IMAP_RESULT_OK. A return value of IMAP_RESULT_CONTINUE indicates the command was accepted and the caller should proceed with the next command. If an error occurs, the method returns IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

A list of valid commands can be found in the technical specification for the protocol. The current version of the protocol which is supported by this library is version 4rev1 as defined in RFC 3501.

Use the **GetResultCode** method to determine the result of the command that was sent to the server.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: cstools11.h

Import Library: csmapv11.lib

Unicode: Implemented as Unicode and ANSI versions

[GetResultCode](#), [GetResultString](#)

CImapClient::Connect Method

```

    BOOL Connect(
        LPCTSTR lpszHostName,
        UINT nRemotePort,
        UINT nTimeout,
        DWORD dwOptions
    );

```

The **Connect** method is used to establish a connection with the server.

Parameters

lpszHostName

A pointer to a null terminated string which specifies the host name or IP address of the IMAP server.

nRemotePort

The port number the client should use to establish the connection. A value of zero specifies that default port 143 should be used, which is the standard port number assigned to the IMAP service. If the secure port number is specified, an implicit TLS connection will be established by default.

nTimeout

The number of seconds that the client will wait for a response from the server before failing the current operation.

dwOptions

An unsigned integer value which specifies one or more options. This parameter is constructed by using a bitwise operator with any of the following values:

Value	Description
IMAP_OPTION_NONE	No connection options specified. A standard connection to the server will be established using the specified host name and port number.
IMAP_OPTION_IDENTIFY	This option specifies the client should identify itself to the server. If enabled, the client will send the ID command to the server as defined in RFC 2971. This option has no effect if the server does not support the ID command.
IMAP_OPTION_TUNNEL	This option specifies that a tunneled TCP connection and/or port-forwarding is being used to establish the connection to the server. This changes the behavior of the client with regards to internal checks of the destination IP address and remote port number, default capability selection and how the connection is established.
IMAP_OPTION_TRUSTEDSITE	This option specifies the server is trusted. The server certificate will not be validated and the connection will always be permitted. This option only affects connections using the TLS protocol.
IMAP_OPTION_SECURE	This option specifies that a secure connection should be established with the server and requires that the

	server support the TLS protocol. This option is the same as specifying IMAP_OPTION_SECURE_EXPLICIT, which initiates the secure session using the STARTTLS command.
IMAP_OPTION_SECURE_EXPLICIT	This option specifies the client should attempt to establish a secure connection with the server. The server must support secure connections using the TLS protocol and the STARTTLS command.
IMAP_OPTION_SECURE_IMPLICIT	This option specifies the client should attempt to establish a secure connection with the server. The server must support secure connections using the TLS protocol, and the secure session must be negotiated immediately after the connection has been established.
IMAP_OPTION_SECURE_FALLBACK	This option specifies the client should permit the use of less secure cipher suites for compatibility with legacy servers. If this option is specified, the client will allow connections using TLS 1.0 and cipher suites that use RC4, MD5 and SHA1.
IMAP_OPTION_PREFER_IPV6	This option specifies the client should prefer the use of IPv6 if the server hostname can be resolved to both an IPv6 and IPv4 address. This option is ignored if the local system does not have IPv6 enabled, or when the hostname can only be resolved to an IPv4 address. If the server hostname can only be resolved to an IPv6 address, the client will attempt to establish a connection using IPv6 regardless if this option has been specified.
IMAP_OPTION_FREETHREAD	This option specifies that this instance of the class may be used by any thread, and is not limited to the thread which created it. The application is responsible for ensuring that access to the class instance is synchronized across multiple threads.

hEventWnd

The handle to the asynchronous notification window. This window receives messages which notify the client of various asynchronous client events that occur. Specifying this parameter and a message identifier causes the connection to be non-blocking. If this parameter is NULL, then a blocking connection is established.

uEventMsg

The message identifier that is used when an asynchronous client event occurs. This value should be greater than WM_USER as defined in the Windows header files. If the ***hEventWnd*** parameter is NULL, this parameter should be specified as WM_NULL.

Return Value

If the method succeeds, the return value is non-zero. If the method fails, the return value is zero. To get extended error information, call **GetLastError**.

Remarks

This method will block the current thread until a connection has been established or the timeout period has elapsed. To prevent it from blocking the main user interface thread, the application should create a background worker thread and establish a connection by calling the **Connect** method in that thread. If the application requires multiple simultaneous connections, it is recommended you create a worker thread for each connection.

The *dwOptions* argument can be used to specify the threading model that is used by the class when a connection is established. By default, the client session is initially attached to the thread that created it. From that point on, until the connection is terminated, only the owner may invoke methods in that instance of the class. The ownership of the class instance may be transferred from one thread to another using the **AttachThread** method.

Specifying the IMAP_OPTION_FREETHREAD option enables any thread to call methods in any instance of the class, regardless of which thread created it. It is important to note that this option disables certain internal safety checks which are performed by the class and may result in unexpected behavior unless access to the class instance is synchronized. If one thread calls a method in the class, it must ensure that no other thread will call another method at the same time using the same instance.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[Disconnect](#), [Login](#), [RegisterEvent](#), [SelectMailbox](#)

CImapClient::CopyMessage Method

```
INT CopyMessage(  
    UINT nMessageId,  
    LPCTSTR lpszMailbox  
);
```

The **CopyMessage** method copies a message from the current mailbox to the specified mailbox. The message is appended to the mailbox, and the message flags and internal date are preserved.

Parameters

nMessageId

The message identifier which specifies which message is to be copied to the mailbox. This value must be greater than zero and specify a valid message number.

lpszMailbox

A pointer to a string which specifies the name of the mailbox that the message will be copied to. The mailbox must already exist, and the client must have the appropriate access rights to modify the mailbox.

Return Value

If the method succeeds, it returns a value of zero. If an error occurs, the method returns IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the mailbox does not exist, the method will fail. To create a new mailbox, use the **CreateMailbox** method. A message can be copied within the same mailbox, in which case the server may flag it as a new message.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[CreateMailbox](#), [GetResultCode](#), [GetResultString](#)

CImapClient::CreateMailbox Method

```
INT CreateMailbox(  
    LPCTSTR lpszMailbox  
);
```

The **CreateMailbox** method creates a new mailbox on the server.

Parameters

lpszMailbox

A pointer to a string which specifies the new mailbox to be created.

Return Value

If the method succeeds, it returns a value of zero. If an error occurs, the method returns IMAP_ERROR. To get extended error information, call **GetLastError**.

Remarks

If the mailbox name is suffixed with the server's hierarchy delimiter, this indicates to the server that the client intends to create mailbox names under the specified name in the hierarchy. If superior hierarchical names are specified in the mailbox name, then the server may automatically create them as needed. For example, if the mailbox name "Mail/Office/Projects" is specified and "Mail/Office" does not exist, it may be automatically created by the server.

The special mailbox name INBOX is reserved, and cannot be created. It is recommended that mailbox names only consist of printable ASCII characters, and the special characters "*" and "%" should be avoided. If you need to create a mailbox which contains Unicode characters or symbols, your application should be compiled to use the Unicode character set to ensure that the mailbox name is encoded correctly. If you do not use Unicode, this method will only accept mailbox names using either modified UTF-7 encoding or UTF-8 encoding.

Requirements

Minimum Desktop Platform: Windows 7 Service Pack 1

Minimum Server Platform: Windows Server 2008 R2 Service Pack 1

Header File: ctools11.h

Import Library: csmapi11.lib

Unicode: Implemented as Unicode and ANSI versions

See Also

[DeleteMailbox](#), [GetFirstMailbox](#), [GetNextMailbox](#), [RenameMailbox](#)

CImapClient::CreateMessage Method

```
INT CreateMessage(  
    LPCTSTR lpszMailbox,  
    LPBYTE lpMessage,  
    DWORD dwMessageSize,  
    DWORD dwFlags  
);  
  
INT CreateMessage(  
    LPCTSTR lpszMailbox,  
    LPCTSTR lpszMessage,  
    DWORD dwFlags  
);
```

The **CreateMessage** method creates a message, appending it to the contents of the specified mailbox.

Parameters

lpszMailbox

A pointer to a string which specifies the name of the mailbox that the message will be created in. The mailbox must already exist, and the client must have the appropriate access rights to modify the mailbox.

lpMessage

A pointer to the buffer which contains the data for the message to be created. An alternate form of the method accepts a pointer to a string.

dwMessageSize

An unsigned integer value which specifies the size of the message data in bytes.

dwFlags
